Bromoacetaldehyde may be obtained by the bromination of paraldehyde at low temperature. The compound is a lachrymator and very quickly becomes viscous and forms a white solid polymer. Acetaldehyde retards the polymerization.<sup>142</sup> Dichloroacetaldehyde assumes a dense form and finally becomes a white amorphous mass with an outward semblance of porcelain. On warming to 120°C., it is reconverted to the liquid.<sup>143</sup>  $\beta$ -Bromobutyraldehyde likewise polymerizes rapidly.<sup>144</sup> Benzylbromoacetaldehyde<sup>145</sup> is an unstable oil readily resinifying and polymerizing on standing; it yields a crystalline monohydrate.

Acraldehyde on halogenation in dilute aqueous solution gives the  $\alpha$ -mono-halogenated aldehydes. The  $\alpha$ -iodoacraldehyde (2-iodo-2-propenal-1) quickly becomes viscous.<sup>146</sup>

#### HYDROXY ALDEHYDES

Levene and Watti<sup>147</sup> prepared several  $\alpha$ -hydroxyaldehydes, namely; 2-hydroxypropanal-1, 2-hydroxybutanal-1 and 2-hydroxypentanal-1. These were mobile liquids when freshly distilled but polymerized rapidly at room temperature to

viscous liquids.  $\beta$ -Hydroxypropionaldehyde (3-hydroxy-1-propanal) polymerized at 90°C. under 18 mm. pressure.<sup>148</sup> d-4-Methylhexan-1-ol-6-al is a viscous amorphous substance.<sup>149</sup>

Gelation is recorded by Evans and Hass<sup>150</sup> as taking place under appropriate temperature conditions during the preparation of glyceric aldehyde acetal. The procedure consists of the oxidation of acrolein-acetal with potassium permanganate.

Dry hydrogen chloride when passed into isobutyraldehyde gives a heavy-bodied oil which resinifies with alkalis.<sup>151</sup> The condensation of isobutanol in the presence of potassium hydroxide produces an aldol which thickens on aging.<sup>152</sup>

### DIALDEHYDES

Glyoxal (CHO-CHO) when evaporated on a steam bath from an aqueous solution produces a water-containing amorphous solid. After drying in a vacuum at 110-120°C., the product polymerizes easily.<sup>153</sup> A yellowish-green vapor was noticed in the preparation of monomeric glyoxal; the color disappeared at room temperature, however, and a white mist was formed, an indication of rapid polymerization.<sup>154</sup>

Methyl glyoxal polymerized with the evolution of heat. Depolymerization could be effected by distillation.<sup>155</sup> Fischer and Taube<sup>156</sup> state that this liquid is green and that polymerization (as noticeable by a thickening of the liquid) sets in a few minutes after distillation. After a lapse of several hours, the product is a brittle, resin-like mass. Polymeric acetaldehyde on oxidation with aqueous nitric acid or analogous oxidizing agents leads to a glyoxal type of resin.<sup>157</sup>

Casein and other albuminous substances may be hardened by means of glyoxal or a condensation product. Electrical insulating and glass-like materials are said to be obtained.<sup>158</sup>

Mucono-dialdehyde (2,4-hexadien-1,6-dial) is very sensitive toward alkalis, the smallest trace of which turns the solution dark brown. Reduction of the aldehyde gives dark polymerization products, whereas oxidation, water-insoluble dark brown tars.<sup>159</sup> 1,10-Decandial,  $\text{OHC}-(\text{CH}_2)_8-\text{CHO}$ , also known as sebacic aldehyde, is a colorless oily liquid of pleasant odor. When freshly distilled and in the absence of a diluent, the aldehyde readily polymerizes to a glassy modification which does not give the typical aldehyde reactions.<sup>160</sup> Similarly, acetone-dihydroxysuccinic dialdehyde (acetone-1-tartaric dialdehyde) is a liquid which solidifies to a glassy mass.<sup>161</sup>

### BENZALDEHYDE AND OTHER AROMATIC ALDEHYDES

Benzaldehyde has somewhat less tendency to polymerize than formaldehyde and acetaldehyde. Its auto-reaction, that is, the formation of carbon-carbon

bonds such as the benzoin condensation, takes place only under the influence of catalysts or by the action of light. A compound similar to the paraldehyde of acetaldehyde, where carbon-oxygen-carbon bonds are formed, does not exist.<sup>123</sup>

It is not surprising therefore that the resinification of benzaldehyde is almost unknown. In alkaline solution the Cannizzaro reaction predominates. In acid solution, with sulphuric acid or with sulphuric-nitric acid, sulphonation and nitration take place. Ciamician and Silber,<sup>124</sup> however, obtained resins by the action of light on benzaldehyde. In one series of experiments they used pure benzaldehyde; in another they dissolved the aldehyde in alcohol. In both cases the samples were exposed to sunlight for three or four months at a time and resinous products were obtained. In one of a series of experiments 35 g. of benzaldehyde were utilized and after exposure the product was partially purified by steam distillation in order to remove unchanged benzaldehyde to yield 26 g. of solid resinous substance. When dissolved in ether, washed with sodium carbonate solution and evaporated to dryness, it was again taken up into solution, this time in benzene. Precipitation with petroleum ether gave a white pulverulent substance of melting point of 125-130°C. and which had the same elementary composition as benzaldehyde. In benzene the molecular formula was found to be represented by  $(C_7H_6O)_n$ .

The alcoholic-benzaldehyde solution, after exposure to light, was washed with benzene. This solution yielded both benzoin and hydrobenzoin on purification. The resin could be obtained from the benzene solution by the same means, precipitation with petroleum ether. This product has a molecular weight which corresponds to  $(C_{14}H_{12}O_2)_n$ , or four hydrobenzoin molecules.

When benzaldehyde (3 mols) is added to magnesium (1 at. wt.) and magnesium iodide in ether and benzene, and the resulting solution hydrolyzed with dilute acid, unchanged aldehyde, benzyl alcohol, benzoin and resinous material are obtained. If an excess of magnesium is used, benzyl alcohol and resinous material are the only products.<sup>125</sup> A mixture of benzaldehyde and acetic anhydride allowed to stand exposed to light reacts, yielding as one product a yellow resin.<sup>126</sup>

The reaction of benzaldehyde and metallic sodium forms in addition to other products a gummy residue part of which was identified as benzoin.<sup>126</sup> According to Kuhn and Ishikawa,<sup>127</sup> the attempts to condense benzaldehyde with crotonic acid resulted in the formation of resinous substances.

Benzaldehyde and dehydrocholic acid react in caustic soda solution to yield a solid soap-like mass which, on acidification with acetic acid, is obtained as an amorphous body that cannot be crystallized.<sup>128</sup> The substance sinters at 195°C. and on further heating gradually melts. The reaction of benzaldehyde, deoxybenzoin and aniline produces a resin.<sup>129</sup> Ciamician and Silber<sup>130</sup> obtained resinous products from the reaction of benzaldehyde, safrol and isosafrol under the influence of light.

Gentisaldehyde, m-hydroxybenzaldehyde, when treated with potassium persulphate in alkaline solution and strongly acidified furnishes a dark brown amorphous substance, which chars above 330°C. and is almost insoluble in all organic sol-

<sup>123</sup> In the Cannizzaro reaction with benzaldehyde a carbon-oxygen-carbon bond is formed; it is possible that the carbon-oxygen-carbon polymerization product is the intermediate of this reaction.

vents except boiling glacial acetic acid.<sup>171</sup> Benzaldehyde cyanohydrin on standing yields resinous products which are probably polymers of benzoin.<sup>172</sup>

Raiford and Talbot,<sup>173</sup> in a study of the effect of substituents in certain condensations of benzaldehyde, treated 3,4-dimethoxybenzaldehyde and 5-bromo-3,4-dimethoxybenzaldehyde with potassium cyanide. In each case a viscous polymerization product was obtained as a residue, which was assumed to be a polymer of the benzoin of the corresponding substituted benzaldehyde. Secareanu,<sup>174</sup> in a study of the lability of nitro groups in the benzaldehyde nucleus, boiled solutions of o-nitrobenzaldehyde, 2,4-dinitrobenzaldehyde or 2,4,6-trinitrobenzaldehyde with benzyl chloride. Hydrogen chloride and nitrogen oxides were evolved and resinous products obtained. Anisaldehyde and dehydrocholic acid yield a dark yellow resin.<sup>175</sup> Benzylidenepyruvic acid (obtained by condensation of benzaldehyde with pyruvic acid in the presence of hydrochloric acid), when dried in vacuum at 25°C., becomes an amorphous solid, which softens at 80°C. and on further heating decomposes.<sup>176</sup> Ciamician and Silber<sup>177</sup> found a mixture of anisaldehyde, benzoin, benzophenone and formic acid to become partially resinified on exposure to light. Benzil dissolved in ethyl alcohol also yielded a resin when similarly treated.

The action of a mixture of acetic acid and acetic anhydride containing sulphuric acid on piperonal and vanillin produces dark-colored condensation products.<sup>178</sup> 4,6-Dinitro-m-xylene, when reacted with aldehydes in the presence of sodium alcoholate, forms resinous substances.<sup>179</sup> Resinification also occurs when p-dimethylaminobenzaldehyde and cinnamaldehyde, or its bromine derivative, are condensed with 4,6-dinitro-m-xylene. König, Schramek and Rösch<sup>180</sup> report the copious formation of acetaldehyde resin when p-dimethylaminobenzaldehyde reacted with paraldehyde or acetaldehyde in the presence of concentrated sulphuric acid. Resins are obtained from benzoylacetone with pyridine as the condensing agent, in benzene-ligroin solution, with the following aldehydes: anisaldehyde, piperonal and m-nitrobenzaldehyde. Reaction of aniline, formaldehyde and desoxybenzoin yields a resin.<sup>181</sup> Phenyl-o-anisylacetaldehyde, phenyl-m-anisylacetaldehyde and 2,4'-dimethoxydiphenylacetaldehyde are easily resinified on distillation even under reduced pressure.<sup>182</sup> When carrying out the reaction between isovaleric aldehyde and salicylic amide, it is necessary to keep the temperature below 70°C. otherwise the aldehyde is largely resinified.<sup>183</sup> Several attempts were made by Curtis and co-workers<sup>184</sup> to condense isovaleric aldehyde with cyanoacetamide, but only a small amount of sticky solid was obtained.

Two hundred grams of cinnamaldehyde and 50 g. of potassium hydroxide in 1700 cc. of water were heated 8 hours at 100°C.; after steam distillation of the residue 120 g. of resin were found.<sup>184a</sup> Formaldehyde reacts with cinnamic aldehyde in the presence of calcium or barium hydrates, at temperatures above 50°C., to yield a resin.<sup>186</sup> The action of chloroform and sodium hydroxide on salicylic acid

is accompanied by the production of some tarry matter.<sup>186</sup> Salicylaldehyde forms a resinous substance when warmed with aniline and methyl phenyl diketone

in alcohol. In the making of protocatechuic aldehyde from catechol, chloroform and caustic soda, a black resin is formed.<sup>187</sup> The preparation of tetrahydronaphthalene aldehyde takes place with much resinification.<sup>188</sup> Piperonylmethylpropylene glycol undergoes resinification with concentrated sulphuric acid (sp. gr. 1.84) even at  $-20^\circ\text{C}$ .<sup>189</sup> One hundred grams of cinnamaldehyde and 100 g. of amylene were exposed to sunlight in a glass tube for 3 months by Alujevich.<sup>190</sup> The product is described as a tarry residue. 1,3-Diphenylpropene ( $\text{C}_6\text{H}_5-\text{CH}=\text{CH}-\text{C}_6\text{H}_5$ ) on oxidation with permanganate yields a glycol which resinifies on the addition of ammoniacal silver solution. This is ascribed by Stoermer and Thier<sup>191</sup> to the formation of 1,2-diphenylpropionaldehyde.<sup>192</sup> 7-Phenyl-2,4,6-heptatrienal-1 ( $\text{C}_6\text{H}_5-(\text{CH}=\text{CH})_3-\text{CHO}$ ) reacts with p-anisidine and with p-phenetidine to form crystalline derivatives, which on treatment with ammoniacal silver nitrate, yield acids which resinify quickly.<sup>193</sup> The phenylhydrazone of  $\alpha$ -bromocinnamaldehyde is resinified by hot acetic acid.<sup>194</sup> The phenylhydrazone of 2,4,6-octatrienal-1 ( $\text{CH}_3-(\text{CH}=\text{CH})_3-\text{CHO}$ ) polymerizes in an inert atmosphere in a few hours.<sup>195</sup>

Hodgson and Jenkinson<sup>196</sup> conducted the Reimer-Tiemann reaction on a solution of resorcinol monomethyl ether. A considerable amount of resinous material was formed. On shaking a cold saturated solution of benzoin in pyridine with solid sodium cyanide, Lachmann<sup>197</sup> observed gradual gel formation. Two grams of finely crystallized sodium cyanide were added to a cold solution of 10 g. of benzoin in 60 cc. of pyridine dried over sodium and the mixture gently shaken. Gel formation took place slowly and the product, upon standing overnight, did not dissolve when warmed to  $35-40^\circ\text{C}$ . It is considered to be an addition product of benzoin and sodium cyanide, but the benzoin content was subject to wide variations, analysis revealing figures ranging from 23-43 per cent. An equimolecular addition product would call for a benzoin content of 81 per cent. The gel is readily hydrolyzed by water or ethyl alcohol. Potassium cyanide fails to give gel formation.

$\alpha$ -Naphthaldehyde when heated with succinic anhydride and anhydrous sodium acetate above  $122^\circ\text{C}$ . results in the formation of tar which renders difficult the purification of  $\alpha$ -naphthylparaconic acid.<sup>198</sup> The semicarbazone of dicyclohexylacetaldehyde was resinified by heating with 55 per cent sulphuric acid.<sup>199</sup>  $\alpha$ -Campholenic aldehyde,

is easily resinified by alkalis.<sup>300</sup>  $\alpha$ -Homoheliotropin<sup>301</sup> is a light yellow oil which resinifies easily by the action of heat, air and alkali.

Reduction of 2-nitro-2-(hydroxymethyl)-1,4-butanediolone with sodium amalgam in aluminum sulphate solution yielded the hydroxylamine derivative as a clear brownish-yellow uncrystallizable gum.<sup>302</sup>

#### PREPARATION AND PROPERTIES OF FORMALDEHYDE ✓

Commercial "formalin," a 40 per cent by volume (37 per cent by weight) aqueous solution of formaldehyde, is generally prepared by the oxidation of methyl alcohol. Methyl alcohol vapor mixed with appropriate quantity of air is carefully led over a contact catalyst and the resulting product condensed. The excess of methyl alcohol is removed by distillation.

Formaldehyde is a gas which can be condensed to a liquid boiling at  $-21^\circ\text{C}.$ ; the liquid aldehyde polymerizes at its boiling point. Evaporation of a solution of formaldehyde results in the production of paraform, a polymer of formaldehyde.

The commercial formalin contains not only the simple formaldehyde but also polymeric forms; the latter being insoluble in water, tend to precipitate. To maintain the polymers in solution, methyl alcohol is not entirely removed and a definite quantity, from 6-14 per cent, is allowed to remain. Due to temperature differences between summer and winter, the methyl alcohol content is varied slightly to prevent any precipitation occurring. In addition to the methyl alcohol, there are small amounts of formic acid and also some methylal which arises from the reaction between methyl alcohol and formaldehyde.

One of the largest sources of methyl alcohol for the manufacture of formaldehyde has been the wood distilleries. With the advent of synthetic methanol, the natural source has been curtailed. The greatly increased production of gaseous hydrocarbons (coal gas, natural gas, cracking gas) has led to many investigations to use these substances as raw materials for the preparation of formaldehyde by partial oxidation.<sup>303</sup> Natural gas or gases from the distillation of coal, petroleum or shale when mixed with air, oxygen or carbon dioxide and allowed to react at  $425\text{--}485^\circ\text{C}.$  with a catalyst (platinum, palladium, gold, silver, copper, chromium, manganese, iron, nickel or their oxides), gave rise to alcohols and aldehydes. By appropriate variation of conditions and catalysts, it was possible to carry out the reaction in stages; methane could be oxidized to methanol and in another step to formaldehyde.<sup>304</sup>

#### REACTIONS OF FORMALDEHYDE

Formaldehyde can combine with itself to form compounds of higher molecular weight in two general reactions. The first of these forms a carbon-carbon bond

<sup>300</sup> P. Lipp and F. Lausberg, *Ann.*, 1924, 436, 274; *Chem. Abs.*, 1924, 18, 1837. For constitution of  $\alpha$ -campholenaldehyde see G. Ciamician and P. Silber, *Ber.*, 1910, 43, 1340; *Chem. Abs.*, 1910, 4, 2481.

<sup>303</sup> For further review, see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, 1934.

<sup>304</sup> J. C. Walker, British P. 290,613, 1927 and 295,856, 1927, to Empire Gas and Fuel Co.; *Chem. Abs.*, 1929, 23, 846, 2186. Canadian P. 300,567, 1930; *Chem. Abs.*, 1930, 24, 3516.

and produces a carbohydrate type of molecule; the second proceeds with the elimination of water from molecules of methylene glycol,  $\text{H}_2\text{C}(\text{OH})_2$ , or polymethylene glycols,  $\text{HO}-(\text{CH}_2\text{O})_n-\text{CH}_2\text{OH}$ .<sup>205</sup>

The formation of carbohydrates, first observed by Butlerow,<sup>206</sup> has been studied by Loew,<sup>207</sup> Fischer,<sup>208</sup> H. and A. Euler,<sup>209</sup> Schmalfluss<sup>210</sup> and others. Various condensing agents have been used: calcium hydroxide,<sup>206, 207</sup> magnesium hydroxide,<sup>210</sup> lead oxide,<sup>207</sup> calcium carbonate<sup>209</sup> and the acetates of lead, calcium and magnesium,<sup>207</sup> both at room temperature and at 100°C. Products of the general formula of  $(\text{H}_2\text{CO})_n$  are obtained, along with both acetic acid and methyl alcohol, that is, the Cannizzaro-reaction products of formaldehyde. Further polymerization of the sugar results in the formation of a brown dye but no resinous products.

The products of the second type of polymerization in which carbon-oxygen-carbon bonds are formed are usually white powders which in contrast to the carbohydrate type are rather easily depolymerized by sodium sulphite, alkali or water. Water is needed to promote this second type of polymerization.<sup>211</sup>

Numerous polymers of formaldehyde are known and they have been studied extensively especially by Staudinger<sup>212</sup> in an attempt to elucidate the structure of cellulose.<sup>213</sup> On the basis of the structures of other linear polymers<sup>214</sup> the formula assigned to the formaldehyde polymers<sup>215</sup> is

Paraform<sup>216</sup> is a mixture of polymer homologs where the number of monomeric units varies from 6 to 50 and is ordinarily prepared by the simple evaporation of aqueous formaldehyde solutions.<sup>217</sup>  $\alpha$ -Polyoxymethylene<sup>218</sup> is also a mixture of polymers but the number of monomer units is 100 or greater; it is formed by the action of dehydrating agents upon formaldehyde.  $\beta$ -Polyoxymethylene<sup>219</sup> is obtained by using a higher concentration of sulphuric acid than is necessary to form the  $\alpha$ -compound. The constitution of this polymer is not known exactly; it is similar in most of its physical properties to the  $\alpha$ -derivative and may be a sulphuric-acid derivative of it.

$\gamma$ - and  $\delta$ -Polyoxymethylenes<sup>220</sup> are not true polymers of formaldehyde.  $\gamma$ -Polyoxymethylene appears to be dimethyl ether of the higher polyoxymethylene glycols

It is precipitated along with  $\alpha$ -polyoxymethylene when concentrated sulphuric acid is added to a formaldehyde solution containing methyl alcohol.  $\delta$ -Polyoxymethylene is formed when the  $\gamma$ -polymer is heated with water.

Trioxo-<sup>221</sup> and tetraoxomethylene, made up of three and four molecules of formaldehyde, respectively, have been isolated.  $\epsilon$ -Polyoxymethylene,<sup>222</sup> a white amorphous non-crystalline paper-like substance, is left behind when  $\alpha$ -trioxomethylene is sublimed. Its molecular species is unknown.

It is to be emphasized that all the previously mentioned oxymethylene polymers with the exception of  $\epsilon$ -polyoxymethylene are crystalline substances and while they may be prepared having the consistency of a grease,<sup>223</sup> they are never resinous. Staudinger and Kern<sup>224</sup> have prepared a polymer of formaldehyde which has the properties of a resin (see Fig. 84). This substance is called eu-polyoxymethylene

Fig. 84.—Glass, Film and Fiber Forms of Polyoxymethylene Prepared by H. Staudinger

and is formed by the spontaneous polymerization of pure monomolecular liquid formaldehyde at low temperatures.

The polymerization, when carried out at  $-80^{\circ}\text{C}.$ , especially in oxygen, leads to a clear transparent somewhat brittle glass; at  $-20^{\circ}\text{C}.$  an opaque solid is formed. The eu-polymers formed at lower temperatures ( $-80^{\circ}\text{C}.$ ) become plastic and elastic when heated to  $160\text{--}200^{\circ}\text{C}.$  In this condition they are very viscous and tenacious and can be formed and kneaded. These properties distinguish them very sharply from  $\alpha$ - or  $\beta$ -polyoxymethylene. The polymers formed at  $-20^{\circ}$  can be drawn out into threads 1 meter or more in length and may be pressed into films. The threads can be stretched to about 10 per cent of their length. Films may also be produced by distillation of monomolecular formaldehyde in vacuum, the receiver being at  $-80^{\circ}\text{C}.$  If cooled with liquid air solid monomolecular formaldehyde is produced which shows no tendency to polymerize. The specific gravity of the glass-clear polymer at  $20^{\circ}\text{C}.$  is 1.407. The products show no defi-

tion he says is a chain reaction, while the solution reaction is simply a condensation of methylene glycols. Sauter<sup>228</sup> on the other hand measured the molecular diffraction pattern of eu-polyoxymethylene and also  $\beta$ - and  $\delta$ -polyoxymethylene and

<sup>226</sup> H. Staudinger, *loc. cit.* H. Staudinger and W. Kern, *Ber.*, 1933, 66, 1893.

<sup>228</sup> E. Sauter, *Zeits. physik. Chem.*, 1933, B21, 161, 186; *Chem. Abs.*, 1933, 27, 3867.

came to the conclusion that the eu-polyoxymethylene has a different molecular structure. Walker<sup>227</sup> says that his powder-like polymer dissolved in alkali but does not mention whether it reverted to monomolecular formaldehyde or not.

The study of the magnetic susceptibilities<sup>228</sup> of the four polyoxymethylenes indicates that these derivatives are mixtures of substances having the general formula,  $\text{CH}_2-(\text{O}-\text{CH}_2)_n-\text{O}-\text{CHO}$ . Moreover, the kinetics of the polymerization reactions of aqueous solutions of formaldehyde denote that the oxygen linkings in polymeric formaldehyde are the same as in amides, esters and semi-acetals and that the mechanism of polymerization and depolymerization of formaldehyde in

FIG. 84e—X-Ray Diagram of a eu-Polyoxymethylene Fiber. (H. Staudinger)

water is similar to that of formation and rupture of these linkages. In dilute solution the following equilibria are assumed:

whereas in concentrated solution:

On pyrex-glass the polymerization of formaldehyde is unimolecular at high pressures.<sup>230</sup>

#### REACTIONS OF FORMALDEHYDE WITH CERTAIN OTHER SUBSTANCES

Water-insoluble products are formed by treating water-soluble cellulose alkyl ethers with aldehydes in the presence of catalysts.<sup>231</sup> For example, methylcellulose foil is treated with formaldehyde in potassium hydroxide at 95°C. It is not stated whether the products are resinous.

Bornyl and isobornyl chlorides condense with formaldehyde in the presence of ferric chloride and form black resinous products which are soluble in benzene, ether

<sup>227</sup> F. Walker, *loc. cit*

<sup>229</sup> M. Wadano, C. Trogus and K. Hess, *Ber.*, 1934, 67, 174; *Brit. Chem. Abs. A*, 1934, 493. For the acidic nature of aqueous formaldehyde solution see M. Wadano, *Ber.*, 1934, 67, 191; *Brit. Chem. Abs. A*, 1934, 393.

<sup>230</sup> R. Spence, *J.C.S.*, 1933, 1193.

<sup>231</sup> K. Sponse and G. Balle, German P. 538,686, 1925, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1932, 26, 2316.

and gasoline.<sup>233</sup> Hydrochloric acid is evolved in the process. When the condensation is carried out in sulphuric acid, however, the resinous products are found to be soluble in benzene but insoluble in ether and gasoline.

When sulphuric acid and acetic acid are slowly added to benzoyl chloride and trioxymethylene, a derivative is formed of the structure

Treatment with silver nitrate yields the dinitrate, which with alkali gives rise to a viscous polymer,  $(\text{CH}_2-\text{C}_6\text{H}_4-\text{CH}_2-\text{C}_6\text{H}_4-\text{CH}_2\text{OH})_n$ .<sup>234</sup> The condensation of anethol (p-propenylanisol) with formaldehyde gave the methylene ether of p-methoxyphenylbutyl glycol which resinified when attempts were made to saponify it.<sup>235</sup>

Condensation of 1-borneol with formaldehyde yields resinous products if the reaction is carried out in the cold and in the presence of concentrated sulphuric acid.<sup>235</sup> An oil is obtained if the condensation is carried out with heating and concentrated acids. The oil, when distilled in the presence of sulphuric acid, yields pitches which are soluble in benzene and might be utilized as lacquers.

Solutions of paraformaldehyde when heated in alcohol with zinc oxide or alumina give rise to a formaldehyde polymer which is soluble in organic solvents and which may be used for production of formaldehyde-phenol resins.<sup>236</sup> The acetal prepared from ethyl alcohol and formaldehyde when treated with an excess of magnesium oxide yielded a starch-like substance.<sup>237</sup>

Although the reaction of formaldehyde with tri- and tetra-chloroethylene in the presence of concentrated sulphuric acid produces identifiable products, the reaction of this aldehyde with dichloroethylene,  $\text{H}_2\text{C}=\text{CCl}_2$ , gives only resinous substances.<sup>238</sup>

The hardening of lac from "*Rhus vernicifera*"<sup>239</sup> can be accelerated by pre-boiling in water which may contain a condensing agent such as formaldehyde.<sup>240</sup>

## Chapter 24

### Furfural Resins

Furfural (fural, furfurol, furfuraldehyde) is a heterocyclic aldehyde of the furan series

that exhibits many resin-forming reactions. Döbereiner<sup>1</sup> first obtained this aldehyde as a by-product in the preparation of formic acid by the action of sulphuric acid and manganese dioxide on sugar.<sup>2</sup> Commercially, furfural is obtained by acid hydrolysis of pentosans occurring naturally in vegetable materials such as bran, corncobs, oat hulls, rice hulls and kapok.<sup>3</sup> Oat hulls are employed principally in the large-scale production of furfural (see Fig. 85). The hulls are moistened with dilute sulphuric acid and the mixture heated to 145°C. under pressure. Simultaneously steam is passed through the hot mass, and furfural is separated from the condensed vapors by distillation.<sup>4</sup>

The pure compound is a colorless liquid (sp. gr. 1.16) which boils at 161.7°C., freezes at -38°C. and becomes brown on exposure to air. It dissolves in water, alcohol and ether.<sup>5</sup> Because of its heterocyclic structure (i.e., the presence of the furan ring) furfural exhibits chemical properties markedly different from those

Bonnwitt, *British P.* 138,078, 1920; *J.S.C.I.*, 1920, 39, 541A. The analytical reactions of furfural are discussed by: K. Suminokura and Z. Nakahara, *Trans. Tottori Soc. Agr. Sci.*, 1928, 1, 158; *Chem. Abs.*, 1929, 23, 2908. W. J. Powell and H. Whittaker, *J.S.C.I.*, 1924, 43, 35T.

of the simpler aldehydes. In its reactions, according to Miner, Trickey and Brownlee,<sup>6</sup> furfural resembles formaldehyde on the one hand and benzaldehyde on the other. It should be noted that cumarone (see Chapter 5), a substance readily

polymerized to a resin by concentrated sulphuric acid or aluminum chloride, is a furan derivative (benzofuran).

The combination of furan ring and aldehyde group in the structure of furfural permits it to behave chemically as an aldehyde or as an olefin oxide, or to exhibit

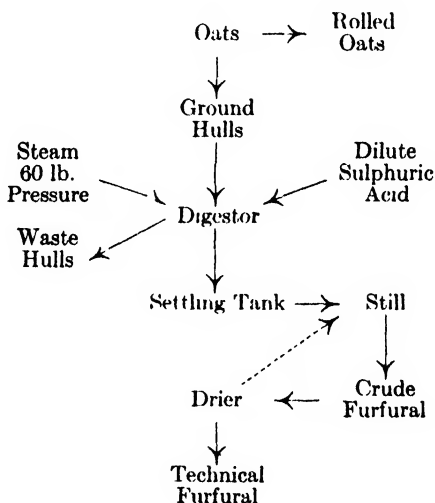

FIG. 85.—Flow Sheet for the Preparation of Furfural from Oat Hulls.

simultaneously the properties of both types of compounds. Like formaldehyde, it reacts with phenols, ketones and amines to give resins; like cumarone, it polymerizes readily. As a consequence, the reactions of furfural are many and diverse.

Furfural is the initial material in the synthesis of a series of compounds containing the furan ring.<sup>7</sup> Thus, furoic acid and furyl alcohol, which have some value as solvents, can be derived from the aldehyde by a Cannizzaro reaction.<sup>8</sup> Kaufmann<sup>9</sup> reduced furfural to furyl alcohol with hydrogen under a pressure of 2

<sup>6</sup> C. S. Miner, J. P. Trickey and H. J. Brownlee, *Chem. Met. Eng.*, 1922, 27, 299.

<sup>7</sup> A discussion of the properties and uses of furfural is given by C. S. Miner, J. P. Trickey and H. Brownlee, *Chem. Met. Eng.*, 1922, 27, 362. For the use of furfural in adhesive compositions, see: H. P. Banks, U. S. P. 1,813,377, July 7, 1931; *Chem. Abs.*, 1931, 25, 5258. F. B. LaForge, *Ind. Eng. Chem.*, 1924, 16, 130. F. B. LaForge, C. <sup>8</sup> H. Schiff, *Ann.*, 1891, 261, 254. H. Lamprecht, *Ann.*, 1873, 165, 254.

<sup>9</sup> W. E. Kaufmann, *J.A.C.S.*, 1923, 45, 3029.

atmospheres in the presence of a platinum oxide catalyst. Furfural diacetate was isolated by Scheibler, Sotscheck and Friese<sup>10</sup> from a reaction mixture containing furfural, acetic anhydride and glacial acetic acid. Furfural combines with chloral-ammonia.<sup>11</sup> It reacts vigorously with nitrous acid to give resinous products. When the aldehyde is dissolved in ether, however, it is apparently unaffected by this acid.<sup>12</sup>

Mahood and Harris<sup>13</sup> condensed m-tolylene-diamine sulphate with furfural in alcoholic solution and obtained tetra-amino-ditolyl-furyl-methane sulphate which could be hydrolyzed by 6 N hydrochloric acid at 140°C. to diamino-dimethyl-furyl-dihydro-acridine. Acetaldehyde and furfural, in the presence of magnesium methoxide or aluminum ethoxide, give isoamyl pyromucate.<sup>14</sup> Substitution of isobutyraldehyde for acetaldehyde furnishes furyl isobutyrate. Phenol and furfural in boiling dilute acid solutions give a 71 per cent yield of a mixture of o- and p-hydrophenyl-furyl-carbinol.<sup>15</sup> In an alkaline solution of sodium sulphite the yield is cut down to 5 per cent.

The resin-forming properties of furfural were noted by Stenhouse<sup>16</sup> in 1840 and Fownes<sup>17</sup> in 1845. Both these workers called attention to the development of resinous bodies when furfural was boiled with acids or alkalis. Persoz<sup>18</sup> and Stenhouse<sup>19</sup> obtained gummy and tarry substances while investigating the action of furfural on aromatic amines and phenols. Claisen,<sup>20</sup> a few years later, produced a brown resin of indefinite composition by treating furfural with  $\beta$ -naphthol in glacial acetic acid solution, using hydrochloric acid as a condensing agent. In none of these cases was any study reported either of the reaction or of the resinous product aside from a superficial examination of its physical properties.

Resin and tar formation is observed in the preparation and reactions of many derivatives of furfural, and this may be taken as an indication of the ease with which compounds of the class undergo condensation and polymerization. Thus, Beaucourt<sup>21</sup> obtained a dark resin on heating furfural and formamide in a stream of carbon dioxide. Hydrogenating furfural in acetic acid, with a zinc-copper couple, gave a little furyl alcohol and a large proportion of resins.<sup>22</sup> Diphenyl-furylmethane, prepared by Mahood and Aldrich,<sup>23</sup> changed into a gum when kept for a few days. Tetrahydro-furfural, in acetic acid solution, combines with phenylhydrazine to form a hydrazone, the latter being an oily substance which easily resinifies.<sup>24</sup> The reaction of methylmagnesium iodide or phenylmagnesium bromide, as well as analogous organo-metallic compounds, with furylacetone was found to yield resinous substances.<sup>25</sup> Yet another example is the oxidation of furan with 6-10 per cent peracetic acid in acetic acid, which gives a resin of the formula  $(C_4H_5O_2)_n$ .<sup>26</sup>

The action of potassium amide, in liquid ammonia solution, on furine

results in the formation of tar and hydrogen.<sup>27</sup> Peters and Fischer<sup>28</sup> prepared a series of alkylfurylcarbinols and found that all such compounds resinified on treatment with phosphorus pentachloride, acetyl chloride, benzoyl chloride, concentrated hydrochloric acid or on exposure to light and air. Nitrogen substituted  $\beta$ -furyl-valeramides have been hydrolyzed to the corresponding acids with 20 per cent alcoholic potassium hydroxide. With concentrated hydrochloric acid, on the other hand, hydrolysis was accompanied with resin formation.<sup>29</sup> A sulphur derivative of furan, 2-furylthiol, sealed in a glass tube and kept for a year, changed into a viscous oil and a white solid,  $(\text{C}_5\text{H}_4\text{OS})_n$ . Pure furan compounds appear to be less likely to change on keeping than impure samples.<sup>30</sup> Kirner<sup>31</sup> reported that on adding thionyl chloride to a mixture of furyl alcohol and pyridine, and heating, a black tar was formed.

This reactivity of furan derivatives is also in evidence in the case of halogenated compounds, as, for example, the transformation of 2-bromomethylfuran into a resin in the cold.<sup>32</sup> Furylbromoethylene resinifies in the air, and furylethylene polymerizes rapidly especially in the presence of oxygen and light.<sup>33</sup> The resinous substance obtained from furan by treatment with acid is converted into humic acids by molten caustic potash.<sup>34</sup> Carter<sup>35</sup> recorded the formation of tars during the preparation of furylmalic acid.

#### GENERAL PROPERTIES OF SEVERAL SPECIES OF FURFURAL RESINS

Synthetic resins from furfural possess several properties that limit their use. In general, they are dark in color and do not harden as rapidly with hexamethylene-tetramine as the phenol-formaldehyde type. Preparative details also present problems, since acid catalysts give insoluble, infusible resins as the result of fast, difficultly-controlled reactions.

Mains and Phillips<sup>36</sup> investigated some of the properties of furfural-amine and furfural-ketone resins. They reported that the products did not have sharp fusion points but softened gradually until fluid. The softening points ranged between 25-100°C., but could be raised by increasing the reaction temperatures or heating the reaction mixture for longer periods of time. All of the resins were practically insoluble in water, somewhat soluble in turpentine, quite soluble in benzene, acetone and alcohol, and very soluble in furfural.<sup>37</sup> The acetone, benzene and furfural solutions gave varnish stains which ranged in color from golden brown to black, depending on the resin type, the concentration of the solution and the number of coats applied. The surfaces thus coated have a glossy appearance.

## POLYMERIZATION OF FURFURAL AND REACTIONS WITH OTHER ALDEHYDES

Furfural, like many other aldehydes, undergoes polymerization on standing. Transformation is slow but can be greatly accelerated by heat or the presence of catalysts. Trickey and Miner<sup>38</sup> treated the aldehyde at 100°C. with ferric chloride, aluminum chloride, lead acetate or iron pyromucate (1 per cent of the weight of furfural). As the reaction proceeded, a soft viscous resin formed first and changed into a fusible, semi-solid mass which was soluble in acetone. On further heating, an infusible solid resulted. Reaction was accelerated by heating under pressure and at higher temperatures.

Metallic iron, nickel, lead, magnesium, zinc or tin in the absence<sup>39</sup> or the presence<sup>40</sup> of an acid also catalyzed polymerization. Thus, 100 parts (by weight) of furfural are mixed with 500 parts of 18 per cent hydrochloric acid, 200 parts of water and 250 parts of iron powder. The mixture is allowed to stand until hydrogen is no longer evolved. The resin is obtained by extraction with alcohol.

When furfural is treated with one-fifth of its weight of concentrated sulphuric acid, it is transformed into a gelatinous material which becomes dense and hard and is characterized by a glossy finish and lustrous fracture.<sup>41</sup> Acids in general cause a similar resinification. Porous products, stated to be nonresinous, are obtained according to Snelling<sup>42</sup> by treating 60 parts of furfural with 15 parts of hydrochloric acid and 25 parts of water for a period of 7 days at room temperature. The soluble components are removed by washing with water, and the residue is suggested for use as an absorbent and in the preparation of artists' crayons.

Alkaline catalysts also effect the resinification of furfural. Meunier<sup>43</sup> refluxed 7 parts of a 17 per cent solution of sodium hydroxide and 1 part by weight of furfural. The solution became dark brown. After heating for an hour, it was acidified with hydrochloric acid which precipitated a black, alcohol-soluble resin. Alcoholic solutions of the latter may be employed for coating purposes, giving a firm glossy surface on drying. Better yields of resin are secured by heating the alkali and aldehyde in an autoclave at 140-150°C. A similar procedure was followed by Mains and Phillips<sup>44</sup> employing a 25 per cent solution of sodium hydroxide and concentrated hydrochloric acid (sp. gr. 1.19).

Resins may be prepared by condensing furfural with acetaldehyde,<sup>45</sup> formaldehyde, benzaldehyde or crotonaldehyde in the presence of hydrochloric acid.<sup>46</sup> As an example, 20 parts (by volume) of technical furfural are mixed with 10 parts of acetaldehyde and 5 parts of concentrated hydrochloric acid and poured into a mold maintained at about 20°C. The mixture turns brownish black and solidifies in 2 days giving a homogeneous solid mass. The cast pieces, which resemble ebonite, are washed free of acid and dried gradually. The final material is insoluble in the common solvents and is resistant to the action of acids and alkalis.

## RESINS FROM VARIOUS FURFURAL DERIVATIVES

Like furfural, furyl alcohol resinifies when heated alone or with a catalyst. In the absence of a catalyst, a temperature of 170°C. is necessary; but with 0.1 per cent of hydrochloric acid polymerization takes place at 80°C.<sup>47</sup> Houtz and Adkins<sup>48</sup> reported that a mixture of the ozonides of two octylenes known as "disobutylene" act as catalysts in the polymerization of furyl alcohol. The furyl alcohol resins are stated to be useful for the impregnation of fibrous materials, incorporation in varnishes or as binders for hot and cold molding operations.

By dissolving furyl alcohol in an equal proportion of furfural with 0.1 per cent of hydrochloric acid and heating to 80°C., Miner and Trickey<sup>49</sup> procured a viscous, tacky resin that could be admixed with fillers. The speed of the reaction and the extent to which it proceeds depends on the temperature employed, which should not exceed 110°C. A related composite resin is also prepared by dissolving a furfural resin in an equal amount of furyl alcohol and heating.

A lacquer composition containing a solution of cellulose nitrate in amyl acetate, a plasticizer (castor oil or shellac), sulphuric or hydrochloric acid and furyl alcohol is described by Fawkes.<sup>50</sup> As the lacquer dries, furyl alcohol is converted into a jet-black material with a glossy finish. Trickey<sup>50</sup> obtained a black color on wood or molded articles by treating with furfural and allowing hydrochloric acid to act on the latter.

Furylethylene may be polymerized by heating for 6 hours at 180-190°C. with catalysts such as benzoyl peroxide, potassium chlorate, ozone or linseed oil acids.<sup>51</sup> Dissolved in toluene together with tricresyl phosphate and nitrocellulose, the resin is used as a coating composition.

## FURFURAL AND PHENOLS

The reaction between furfural and phenols in the presence of acid catalysts yields infusible insoluble resins that frequently have a rubbery nature. The materials exhibit elasticity under compression but possess no tensile strength, thus resembling factice (see Chapter 60). The color of the acid-catalyzed reaction products ranges from brown to black. If aqueous hydrochloric acid is added to a mixture of about equal parts of furfural and phenol, a violent reaction ensues, resulting in the formation of an elastic jelly-like substance or a hard, brittle and infusible resin. The nature of the final material depends upon the proportion of hydrochloric acid employed, temperature and other conditions. Phenol-furfural condensation in the presence of acids is complicated by the fact, already noted, that furfural itself readily polymerizes under these reaction conditions. Inasmuch as the utility of a resin, either in varnishes or plastic compositions, depends upon its being soluble or fusible, the products of the phenol-furfural condensation have only a limited use unless the reaction is carefully controlled. Beckmann and Dehn<sup>52</sup> found, however, that rigid, infusible articles could be made by casting the acid-catalyzed

<sup>53</sup> E. Beckmann and E. Dehn, *Sitzber. preuss. Akad. Wiss., Berlin*, 1918, 1201; *Chem. Abs.*, 1920, 14, 642.

products of the phenol-furfural reaction. The procedure is limited in application, as the hydrochloric acid present attacks the moldwalls and causes the casting to stick.

The problem, then, is to make the primary furfural condensate in a fusible, soluble form so that it may find application in solution or in molding compositions with substances that will effect the final curing on subjection to heat and pressure. When an acid catalyst is used, a phenol-furfural resin having these properties is obtainable only if a large excess of phenol is used initially. Thus, if ten times as much phenol as furfural is employed (with a hydrochloric acid catalyst), a liquid is obtained from which the excess phenol may be removed by steam distillation leaving a black, fusible resin. Beckmann and Dehn<sup>55</sup> found that equal parts of furfural and phenol represent the combining proportions for resinification. The addition of strong acid to such a mixture, however, gives an infusible product. Although dilution with phenol results in the formation of soluble, fusible resins, such is not the case with many other organic liquids used as diluents. The action appears to be a specific one for phenol and a few other substances. The large proportion of phenol required materially increases the cost of production.

As furfural may be obtained almost water-free, phenol-furfural resins in contrast to the phenol-formaldehyde types can be prepared in the absence of water, save that formed during condensation. Because of their dark color, the resins can be applied in insulation without the addition of pigments which might tend to impair their electrical properties.

Beckmann and Dehn<sup>56</sup> added concentrated hydrochloric acid to a solution of phenol and furfural and noted that a reddish-violet color changing to dark blue appeared. The mixture becomes hot and finally solidifies to a hard black mass insoluble in acids, alkalies, chloroform, acetone or benzene and unaffected by boiling. The product is scratched slightly by gypsum and strongly by calcite and thus corresponds in hardness to Bakelite C. It possesses some elasticity, breaking with difficulty. The fracture is conchoidal. The resin can be turned on a lathe but attacks metals because of the phenol and acid present. This defect is overcome by heating, which makes the material harder but more brittle.

Beckmann and Dehn studied various mixtures of furfural and phenol to determine the most reactive proportions. The results of these observations are shown in Table 31. It was noticed that after addition of the acid solidification took place first along the walls of the vessel and the surface of the liquid. As a result of a series of experiments it was concluded (as already noted) that the best resin-forming proportions were equal parts of furfural and phenol. A study of a solution of this composition showed that the speed of reaction increased rapidly as the concentration of the acid was raised over a small range. Other reactions of furfural in the presence of hydrochloric acid with hydroxyl-containing aromatic compounds and terpenes were determined by Beckmann and Dehn, and the results were as follows:

1. *o-Cresol*. The solution becomes blue-violet and heats spontaneously, soon solidifying to a black product.

2. *m-Cresol*. This likewise heats but becomes dark blue and condenses to a black solid.

3. *p-Cresol*. The solution becomes green, then blue and finally black. It remains liquid longer than the two other cresols but condenses to a solid substance. It does not heat spontaneously.

4. *Crude Cresol*. (From tar oil.) The solution heats strongly, becoming reddish-violet; and after about an hour becomes hard and black.

<sup>56</sup> E. Beckmann and E. Dehn, *loc. cit.*

TABLE 31.—*Reactions of Phenol and Furfural.*

Duration of Treatment	10% Furfural	20% Furfural	30% Furfural	40% Furfural	50% Furfural	60% Furfural	75% Furfural
10 min.	initial coloration blue changing to dark green						
1 hour	black, liquid, soluble in alcohol with dark green color	black, liquid, almost completely soluble in alcohol with brown color	black, liquid, partly soluble in alcohol with brown color	black, liquid, only partly soluble in alcohol with brown color	black, solid, elastic, almost insoluble in alcohol (dark green color)	black, liquid, partially soluble in alcohol with greenish black color	black, liquid, partially soluble in alcohol with greenish black color
2 hours	liquid	liquid	liquid	solid, elastic	solid, less elastic	solid, elastic like 40% furfural	solid, elastic like 60% furfural
3 hours	liquid soluble in alcohol	liquid	liquid	solid	solid	solid	solid
3.5 hours		liquid	solid, like gelatine	solid	solid	solid	solid
5.5 hours		liquid, almost wholly soluble in alcohol	solid, very elastic	solid	solid	solid	solid
7 hours		liquid	solid	solid	solid	solid	solid
8 hours		liquid	solid	solid	solid	solid	solid
24 hours		solid, like gelatine, almost insoluble in alcohol	solid	solid	solid	solid	solid
30 hours		solid	solid	solid	solid	solid	solid

5. *Thymol*. The solution changes from blue to black and soon thickens to a solid. There is no spontaneous heating.

6. *Pyrocatechol*. The solution turns gradually with spontaneous heating from a reddish-violet to blue and then to black. The separated solid condensation product is lustrous and shows a slight separation of pyrocatechol.

7. *Resorcinol*. The solution reacts immediately and violently with ebullition on the addition of hydrochloric acid. A solid substance, full of bubbles, separates.

8. *Hydroquinone*. One part of hydroquinone dissolves completely in an equal amount of furfural on heating. Hydrochloric acid is added to the warm solution and after cooling, a solid black substance is found, to the surface of which some separated hydroquinone is clinging.

9. *Guaiacol*. At the beginning the solution is brown but becomes black, remaining liquid for a long time and finally solidifying. The solution does not heat spontaneously.

10. *Pyrogallol*. Reaction takes place violently with blackening and the rapid formation of a vesiculated mass.

11. *Phloroglucinol*. It dissolves in furfural only on heating. The addition of hydrochloric acid to the hot solution brings about a violent reaction with ebullition and the separation of a vesiculated brittle substance.

12. *m-Chlorophenol*. The solution becomes dark green and reacts slowly, condensing finally to a hard lustrous solid. There is no heating.

13. *p-Chlorophenol*. The solution becomes dirty gray and eventually black, with the separation of a soft and friable substance.

14. *o-Nitrophenol*. A yellowish-green oil separates, which remains liquid and shows only slight indications of black particles. There is no evolution of heat.

15. *p-Nitrophenol*. The solution becomes brown and then black without the evolution of heat. It remains liquid for a long time but finally solidifies to a product which is not homogeneous. It is admixed with unchanged nitrophenol and is friable.

16. *Picric Acid*. There is no visible reaction even on warming. The dark green mixture remains liquid.

17. *p-Amidophenol*. This dissolves in furfural only on heating and reacts without the addition of acid.

18. *Menthol*. A green solution which becomes darker on warming and then black is produced. Finally a black spongy mass separates which does not become solid.

19. *Terpineol*. The solution becomes brown without spontaneous heating. Later its color turns red and a solid is formed.

20. *Carvacrol*. A reddish-violet solution is yielded which soon heats spontaneously and after 2 hours becomes solid. The product is fairly hard.

21. *Camphor*. The solution reacts very slowly with a reddish-violet coloration, gradually becoming brownish.

22. *Borneol*. Borneol (1 part) dissolves completely in the cold in 2 parts of furfural. The solution is colored violet on the addition of hydrochloric acid, then brownish-black while a solid substance separates. There is no self-heating, and unchanged borneol remains.

23.  *$\alpha$ -Naphthol*. The solution immediately becomes red, turning to violet; and with a violent, almost explosive reaction, changes to a black solid. It is unusually hard but vesiculated.

24.  *$\beta$ -Naphthol*. It reacts immediately with the appearance of a dark blue coloration, but the reaction is less violent than in the case of  $\alpha$ -naphthol. However, there is a strong evolution of heat. The reaction product is hard and lustrous

In certain instances, substitution in the para position with respect to the hydroxyl group appears to be unfavorable for condensation.

Of the foregoing products the most promising ones were from phenol, crude cresol, guaiacol, carvacrol and  $\beta$ -naphthol. All were made in the proportion of 10 parts furfural, 10 parts of the phenolic substance and 1 part of concentrated hydrochloric acid. In manufacturing these resins on a large scale, probably only the products from phenol and crude cresol (or possibly naphthol) can be considered because of the cost.

In place of aqueous acid, alcoholic hydrochloric acid may be used to produce firm black bodies. These have a conchoidal fracture and machine well, but differ from those made in aqueous acid by having a lustrous surface of fracture through-

out the mass instead of in the outer zone only. Other inorganic acids may be employed, but organic acids as acetic, tartaric and benzoic acid (with the possible exception of oxalic acid), exhibit little catalytic action, and the solution of reactants remains liquid even after heating for a long time. Reaction mixtures treated with acetic and benzoic acid did not show a black coloration.

It was noticed in 1872 by Baeyer<sup>54</sup> that an indigo-blue substance, soluble in water, precipitated from mixtures of furfural and phenol, resorcinol and pyrogallol acid on the addition of hydrochloric acid. Steinitzer<sup>55</sup> obtained a hard-rubber substitute by heating 100 g. of furfural, 50-100 g. of phenol and 3 g. of concentrated sulphuric acid in a closed mold at 150°C.

Trickey, Miner and Brownlee<sup>56</sup> found oxalic acid to be less active as a catalyst than sulphuric or hydrochloric acids. External heat was necessary to cause reaction. The results of their observations on hydrochloric acid as a catalyst are summarized as follows:

1. In order to obtain an infusible, insoluble resin the proportions should be preferably slightly in excess of 1 mol furfural to 1 mol phenol.

2. The resin obtained with an excess of phenol was soluble in acetone and alcohol, and remained jelly-like when cooled, even after it had been heated for a number of days.

3. The resins obtained with varying amounts of acid as a condensing agent were similar, but the time necessary to complete the reaction varied from 2 weeks in the case of 0.2 per cent to 10 hours in the case of 0.6 per cent acid, indicating that the acid catalyst is most effective within a very narrow range of concentration.

Tzonev and Yavnel<sup>57</sup> reported that condensation products of better quality were prepared by substituting cresols for phenol. The reaction velocity of furfural with phenols increases in the order: quinol, catechol,  $\beta$ -naphthol, phenol, p-cresol, o-cresol, m-cresol,  $\alpha$ -naphthol, resorcinol. These investigators also stated that the hardest resins were formed from the least symmetrical molecules.

Sweeney<sup>58</sup> produced resins by treating corncobs (ground to pass a quarter-inch mesh) with cresol in the presence of 10 per cent of hydrochloric acid. The weight of cresol was about 60 per cent that of the pentosan-containing corncobs. After heating for 3 hours at 100°C., the mixture yields a black sticky mass which sets to a brittle solid in 48 hours and is then molded. The water-solubility of the resin is decreased by heating at 100°C. for several days.

Jet-black resins, which may be used either alone or with filling materials, are made by developing a small quantity of coloring matter in the phenolic reagent (through condensation with a limited portion of furfural) before formaldehyde treatment.<sup>59</sup> Thus, 1 mol of phenol or cresol is mixed with 0.05 mol of furfural and 1 per cent of hydrochloric, sulphuric or oxalic acid. The mixture is boiled until it blackens, 0.6 mol of formaldehyde is added and the heating is continued to complete the reaction. The black resin is soluble in organic solvents and may be used in varnishes. Hexamethylenetetramine may be substituted for formaldehyde as the hardening agent.

As a means of preparing stable resin solutions that would set at a controllable rate on the addition of an acid catalyst, Knapp<sup>60</sup> suggested the use of a mixture of phenol and phenol-formaldehyde condensates with furfural. A composition of

this sort is made by first refluxing 25-175 parts of formaldehyde and 210 parts of phenol in the presence of hydrochloric acid, cooling, removing water and neutralizing the residue. Then, 140 parts of furfural together with 20-30 per cent of a filler (asbestos) are incorporated giving a stable paste. When the composition is to be used, a small proportion of a catalyst consisting of 70 parts of concentrated sulphuric acid and 30 parts of ethyl alcohol is added; and the mass gradually stiffens, remaining workable for about an hour.

Novotny and Kendall<sup>61</sup> also prepared fusible phenolic condensation products by reacting 100 parts of phenol with 15-40 parts of furfural and 5-10 parts of 39 per cent hydrochloric acid under pressure. Considerable heat is developed and cooling is necessary to maintain a temperature of about 93°C. The mixture is agitated for one hour, and is then heated to 166°C. to remove hydrochloric acid and the water formed by the condensation. Unreacted phenol is eliminated by steam or vacuum distillation. Alkali is added to neutralize any traces of acid remaining. The fusible product is mixed with 8-40 per cent of furfuramide; and, after hardening, the resin may be used in powder form or in alcohol or acetone solution. The dry composition becomes rigid and infusible when subjected to pressure at temperatures of 93-177°C.

Cracked petroleum distillates, having a relatively high content of unsaturated hydrocarbons, may be combined<sup>62</sup> with furfural to give synthetic resins. A cracked gasoline fraction (250 parts by volume) refluxed with 150 parts by volume of technical furfural in the presence of 1 per cent by weight of sulphuric acid furnishes a jet-black jelly-like mass that can be mixed with wood flour and molded. Cracked oils pre-treated with air or other oxidizing gases similarly react with furfural yielding resins, the properties of which depend to some extent on the kind and duration of pre-oxidation. By extracting the cracked distillates with liquid sulphur dioxide the more highly unsaturated portion is isolated and may be freed of solvent by evaporation. After mild oxidation, this extract will form a hard resin with furfural. Catalysts suggested for the resin-forming reaction are sulphuric acid, hydrochloric acid, sodium hydroxide and ammonia.

**Chlorides as Condensing Agents.** In view of the activity of hydrochloric acid as a condensing catalyst for the phenol-furfural reaction, other chlorides were investigated by Beckmann and Dehn.<sup>63</sup> Sodium or potassium chloride had no effect even after prolonged boiling; but ammonium chloride and amine hydrochlorides, on the contrary, catalyzed condensation. A black coloration on heating was noted when 10 per cent of ammonium chloride was added to mixtures of furfural and phenol, crude cresol or  $\alpha$ -naphthol. Compositions containing this type of agent, however, remain liquid in spite of prolonged boiling. A phenol-furfural solution to which 10 per cent of hydroxylamine hydrochloride is added undergoes a violent reaction with the formation of a black solid. Aniline hydrochloride is a less effective catalyst. Metallic chlorides of an acidic nature (zinc, aluminum and cuprous chlorides) behave like the amine hydrochlorides. Epichlorohydrin, acetylene tetrachloride and carbon tetrachloride have been suggested also as condensing agents.<sup>64</sup>

**Basic Condensing Agents.** As noted earlier in the chapter, acid catalysts cause the phenol-furfural reaction to proceed rapidly to the formation of infusible products and thus limit their commercial utilization. Basic catalysts, however,

produce a slower, more controllable action by means of which stable intermediate condensates of a fusible and potentially hardenable nature are obtainable. Resins prepared with basic catalysts, therefore, have a greater practical significance.

When equal parts of phenol and furfural are heated with sodium hydroxide, or sodium carbonate solutions, a brown oil forms.<sup>66</sup> The oil thickens on heating for 8 hours at 180°C. in a sealed tube. Under the same conditions a solution of ammonia gives a plastic mass which is soluble in hot alcohol, acetone and chloroform, and is resistant to acids and alkalis. Materials of a similar nature are obtained by heating phenol-furfural mixtures at 100°C. for 3-4 hours with solid alkali hydroxides or carbonates. The brown gummy masses dissolve in organic liquids and, in alcohol and benzene, give clear brown varnishes. They melt easily and at high temperatures become insoluble and infusible, resembling the substances obtained with acids or chlorides.

Trickey, Miner and Brownlee<sup>66</sup> also report fusible furfural resins could be prepared readily by employing alkaline catalysts. Their observations are summarized as follows:

1. In order to obtain an insoluble resin the proportions should be about 1.25 mols of furfural to 1 mol of phenol. With these resins cold-molded products were produced on a commercial scale.

2. The resins formed in an excess of phenol were solid and brittle when hot, melted easily and were readily soluble in acetone, alcohol and furfural.

These investigators stated that sodium hydroxide or the monohydrate of sodium carbonate (1 per cent of the mixture) gave a solution in which the reaction was easily controlled.

Equimolecular proportions of the two reactants in the presence of 4 *N* sodium hydroxide, 3.6 *N* potassium hydroxide or 18 per cent of calcium oxide appeared to give the best yield of a soluble black resin, according to Routala and Kuula.<sup>67</sup> The time required for condensation varied from 2.5 to 4 hours. It was found that furfural resins could be bleached to a considerable degree by halogens.

Nash, Trickey and Miner<sup>68</sup> suggested that a solid catalyst be employed. Thus, a mixture of 94 parts of phenol, 104 parts of furfural and 1 per cent (of the total weight) of sodium carbonate was heated until a stiff plastic mass was formed. When cooled, it could be thinned with additional furfural, admixed with asbestos, molded and finally hardened at 180-230°C.

Two per cent of potassium carbonate (on the basis of the weight of phenol) as a catalyst in the reaction of phenol (100 parts) and furfural (75 parts) were recommended by Novotny and Kendall.<sup>69</sup> The reactants are heated for 2 hours at 130-150°C., water and excess phenol are then removed, and the product is pulverized. The rate of formation of the resin was increased by the addition of about 1 per cent of *p*-phenylenediamine, the solubility of the resin at the same time being decreased. Incorporation of 8 per cent of furfuramide with the powdered resin accelerated its hardening during hot molding.<sup>70</sup> If the reaction mixture is rapidly chilled, condensation is checked and syrupy products are obtained.<sup>71</sup>

These may be stored and resinified as required with hardening agents and filling materials. A golden-brown, alcohol-soluble resin, designed for use in varnishes, is prepared by refluxing for 1.5-2.5 hours a composition containing (by weight) 2600 parts of commercial cresol, 1300 parts of furfural, 1240 parts of formaldehyde and 13 parts of potassium carbonate.<sup>73</sup>

Ellis<sup>73</sup> prepared fusible, alcohol-soluble resins by condensing furfural and phenol in the presence of carbonates.

As an example, 10 parts (by weight) of phenol, 7.5 parts of furfural and 0.5-1 part of sodium or potassium carbonate are mixed and refluxed for 2-3 hours at 150°C. Residual phenol and furfural are then removed by heating to 160-170°C. and blowing steam through the mixture, which also deodorizes the product. During this treatment the resin becomes more viscous and when cool may be powdered. To prepare a molding composition from the resin, 100 parts by weight are dissolved in alcohol and 3-10 parts of hexamethylenetetramine and 100 parts of wood flour are added. The dry mixture may be molded at 160-180°C. under a pressure of 1000-2000 lb. per square inch. An insoluble and infusible resin can be obtained directly by using a larger proportion of furfural and heating for longer periods.

Kurath<sup>74</sup> made a quick-setting resin by permitting phenol to react with furfural in the presence of sodium hydroxide. The mixture is maintained at such a temperature that the water formed during the reaction is continuously removed. In this manner, lowering of the boiling point due to the accumulation of water is avoided and the reaction is quickened.

Interaction of cresol and furfural may be carried out in two stages.<sup>75</sup> In the first, the aldehyde (100 parts by weight) and cresol (100 parts) are refluxed at 110°C. with calcium hydroxide (12 parts) for an hour. This product does not solidify on cooling. In the second stage the hot resin is mixed with an additional 20 parts of calcium hydroxide and the heating is continued at 150°C. for 15 minutes or until a sample forms a hard brittle mass on cooling. Stearic acid, or a non-hardening resin, may be incorporated in the mixture during the second stage.

A reactive phenol-furfural resin may be added to a mixture of calcium oxide and hexamethylenetetramine to form a mass which is said to cure quickly.<sup>76</sup> For example, 100 parts (by weight) of furfural, 100 parts of phenol and 2 parts of sodium carbonate are heated under reflux for 2 hours and then heated in an open vessel to drive off water. The dehydrated resin is mixed with 8 parts of lime and 1-4 parts of hexamethylenetetramine and heated at 140°C. until a viscous fusible resin is produced.

According to Mains<sup>77</sup> commercial coal-tar acid containing about 75 per cent of m- and p-cresol, 20-25 per cent of xylol and a small proportion of o-cresol is superior to cresylic acid for condensation with furfural in the presence of sodium carbonate. A furfural-formaldehyde mixture can be used in place of furfural.

The plasticity and molding quality of phenol-formaldehyde resins may be improved by the incorporation of furfural.<sup>78</sup> Furfural-phenol resins do not show the same reactivity when incorporated with hexamethylenetetramine as do formal-

dehyde-phenol products, hence hardening does not take place rapidly in the mold.<sup>70</sup> Sticking presents another difficulty. Furfural resins have been used in the manufacture of printing plates and matrices, but in these applications it is customary to interpose a thin sheet of tinfoil between the mold and the molded piece to avoid sticking.

The following procedure is suggested by Thompson<sup>70</sup> for securing adhesion between rubber and smooth metal surfaces. A heat-reactive resin (formed by condensing 50 parts by weight of furfural and 50 parts of phenol in the presence of 10 parts of sodium carbonate for 3 hours at 100°C.) is ground and incorporated with powdered rubber. The dry mixture is applied to a metal surface, a layer of vulcanized rubber is added and the whole is vulcanized under pressure.

**Alkaline Salts.** Beckmann and Dehn<sup>71</sup> reported that, in general, alkaline salts did not bring about condensation between phenol and furfural. Numerous tests were made with sodium perchlorate, perborate, thiosulphate and sulphite without obtaining positive results. The solutions of reactants became darker in color on heating but remained liquid. Sodium peroxide ignited the mixture.

**Condensation Without Catalysts.** In the absence of an added catalyst, mixtures of phenol, crude cresol or  $\alpha$ -naphthol and furfural resinify. Beckmann and Dehn<sup>72</sup> heated equal parts of phenol and furfural in a sealed tube for 8 hours at 220°C. The mixture became dark brown, but remained liquid, and was completely soluble in alcohol, acetone and chloroform. A solution composed of equal parts of crude cresol and furfural, heated under the same conditions, gave a thick brownish-black oil containing water globules. The oil was only partly soluble in alcohol but dissolved completely in acetone, chloroform and benzene. When equal parts of  $\alpha$ -naphthol and furfural are heated in a sealed tube for 9 hours at 150°C., a solid product containing bubbles is obtained. This softens without melting and is insoluble in alcohol, acetone, chloroform and benzene.

Novotny<sup>73</sup> also prepared a resin from phenol and furfural without the addition of a catalyst. Equal parts of the reactants give an infusible and insoluble condensation product when heated more than 2 hours at 200-230°C. A fusible material that may be hardened with hexamethylenetetramine is obtained by reducing the heating time to 1 hour and maintaining the same temperature, which is decidedly higher than that (usually not greater than 150°C.) employed with catalysts. Xylenol condenses readily with a mixture of furfural and formaldehyde on refluxing. The temperature in the latter instance is 182-193°C., and water is removed continuously from the condensed vapors by a gravity separator, the reactive ingredients being returned to the digester. The product is admixed with a hardening agent (formaldehyde).<sup>74</sup>

**Modified Furfural Resins. Extending Agents.** A resin designed for use in varnish, molding and insulating compositions is obtained by incorporating phenol-furfural resins with glycerol-phthalic anhydride products.<sup>75</sup> A composition containing a phenol-furfural or aniline-furfural resin, benzene and hydrochloric acid can be used as a protective layer on surfaces coated with cellulose acetate, cellulose nitrate or methyl cellulose.<sup>76</sup> Further condensation of the phenol-furfural resin in sunlight or by baking forms an insoluble, infusible finish that preserves

the cellulose compound from the action of acids, alkalis and heat. A coating composition containing resorcinol dissolved in furfural, tolyl phosphate and cellulose acetate may be resinified on the surface by treatment with hydrogen chloride.<sup>87</sup>

Beckmann and Dehn<sup>88</sup> added 1 part of hydrochloric acid to a cooled solution containing 4 parts of phenol, 4 parts of furfural and 1 part of coal tar. A solid mass similar in properties to the acid-catalyzed resins from phenol and furfural previously described was obtained. A black substance which retained its elasticity up to 100°C. resulted when 5 per cent of lanolin was substituted for the coal-tar. Glycol, glycerol, vaseline, cumarone resin and pyroxylin lacquer could not be used as extending agents because separation occurred during condensation. Sulphur additions gave no beneficial effects.

**Phenol, Furfural and Other Aldehydes.** When equal weights of phenol, formaldehyde and furfural are boiled with 10 per cent of concentrated ammonium hydroxide, a dark liquid separates.<sup>89</sup> Using 10 per cent of aniline hydrochloride, in place of ammonia, somewhat better products are formed. A mixture of phenol, furfural, benzaldehyde and concentrated hydrochloric acid becomes violet and heats spontaneously, gradually becoming black and viscous. The condensate is not solid and yields a soft spongy mass which is partially soluble in organic solvents. A similar but somewhat more solid body is obtained when cresol is substituted for phenol.

Turkington<sup>90</sup> proposed the addition of furfural and a filler to phenol-formaldehyde condensation products in the production of cold-molding compositions. A typical mixture of this sort consists of 40 lb. of finely ground asbestos, 4 lb. of furfural and 8 lb. of phenol-formaldehyde resin. The resin and furfural are first mixed to form a liquid of molasses-like consistency to which the filling material is added.

Incorporation of furfural in phenol-formaldehyde resin varnishes was suggested by Cheetham.<sup>91</sup> As an example, 50 lb. of the resin are dissolved in 100 lb. of alcohol and 20 lb. of furfural. The furfural imparts increased fluidity and penetrating quality to the varnish. The aldehyde also tends to absorb part of the ammonia liberated from hexamethylenetetramine during the setting of the varnish, thus partially preventing the formation of bubbles.

Phenol (50 parts by weight) and formaldehyde (12.5 parts) may be condensed in the presence of hydrochloric acid and treated with furfural (12.5 parts) after removal of water. On heating for 10-12 hours at 80°C., an insoluble resin is obtained.<sup>92</sup> As an alternative, a mixture of phenol, formaldehyde, furfural and catalyst may be stirred together without external heating and allowed to stand. The aqueous layer which settles is separated mechanically, and the mass is heated at 100°C. for a long period. An insoluble resin free from bubble cavities is formed.<sup>93</sup> By allowing a mixture of 50 parts by weight of phenol, 40-60 parts of furfural and 1 part of p-aminophenol to stand and by heating the product (after removing water) for a long period at 70-100°C., an insoluble infusible resin is obtained which may be used in insulation.<sup>94</sup>

Ellis<sup>96</sup> suggested modifying phenol-butyraldehyde<sup>96</sup> resins by heating them at 150°C. with furfural in the presence of potassium carbonate. He also condensed phenol-acetaldehyde resins (containing excess phenol) with furfural, using alkali carbonates as catalysts.<sup>97</sup> If the condensation of phenol, acetaldehyde and furfural is prolonged until the resinous product when cold can be crushed between the fingers to a non-tacky powder, hexamethylenetetramine may be incorporated and the resultant mixture used for molding.<sup>98</sup> In another process a phenol-formaldehyde resin is heated at 130-150°C. with furfural, calcium oxide, a small amount of hexamethylenetetramine and stearic acid until a brittle, fusible product forms on cooling.<sup>99</sup>

Phenol-furfural resins exhibit a strong tendency to gelatinize before condensation is completed. Hence, the product is likely to be incompletely dehydrated and thus inferior for electrical purposes. To avoid this difficulty, Groff<sup>100</sup> suggested reacting phenol and furfural in the presence of sodium hydroxide at 110-160°C. Then, 30-80 per cent of a phenol-formaldehyde or natural resin is added and heating continued at 150°C. with hexamethylenetetramine as a hardening agent. Varnishes for electrical insulation are prepared from the resulting dehydrated resins by dissolving them in alcohol or butyl acetate. Alternatively, 200 lb. of phenol- or cresol-formaldehyde resin are heated to 140-150°C. and to the fluid resin are added 6 lb. of stearic acid and 16 lb. of calcium hydroxide.<sup>101</sup> The mixture is stirred for 15-30 minutes at 130-150°C. and then 30 lb. of furfural are incorporated. Reaction is continued until a test-sample is brittle when cold. Molding compositions are prepared by mixing the product with hexamethylenetetramine and fillers.

Furfural, even in relatively small proportions, exerts considerable influence on the flowing qualities of the final compositions. By using this aldehyde, it is possible to raise the ratio of filler to resin without affecting the molding properties. Thus, a molding mixture containing 25 per cent of a formaldehyde resin, 20 per cent of furfural and 55 per cent of wood flour exhibits substantially the same flowing qualities as a composition containing equal amounts of resin and filler.<sup>102</sup>

Melhus<sup>103</sup> employed a composition containing a fungicide (e.g., mercuric cyanide), a solution of furfural and a furfural-cresol condensation product for the treatment of plant wounds. Furfural is used in abrasive cements, a typical composition containing 90 parts by weight of sand, 10 parts of phenol-formaldehyde resin, 3.3 parts of furfural and 2.5 parts of alcohol.<sup>104</sup> Phenol-furfural resins, like a number of other types, have been suggested for use in brake linings.<sup>105</sup> Thin sheets of asbestos are treated with graphite or talc and bonded with the resin.

**Impregnation of Paper Moldings.** Beckmann and Dehn<sup>106</sup> obtained a hardened waterproof sheet with good insulating properties by impregnating paper with phenol, furfural and 1-2 per cent of hydrochloric acid. The acid did not cause the paper to become brittle. Solutions of the resin in organic solvents may also be employed.

Furfural resins were used by Novotny in the manufacture of printing plates,<sup>107</sup> phonograph records<sup>108</sup> and in the production of a moldable composite body.<sup>109</sup> In each case, the furfural and phenol condensation products are used to impregnate paper, cloth or other fibrous materials. The resulting material is molded in sheet form. Mains<sup>110</sup> prepared an impregnant by allowing a phenol-furfural resin to react with a solution of furfural in tung oil. Further, phenol-furfural binders may be introduced into paper in the course of manufacture. A proposed application of the resultant sheet is the production of bottle closures. A piece of the material is placed over the bottle, crimped down around the lip and heated to harden the resin, thus making a permanent seal.<sup>111</sup>

Punching and shearing of paper treated with furfural condensates is facilitated by incorporating 0.5-2 per cent of paraffin, beeswax or lanolin in the composition, according to Novotny and Romieux.<sup>112</sup> The impregnation of wood with resins derived from phenolic tars and formaldehyde is assisted by the addition of 2-8 per cent of furfural-chloronaphthalene resins.<sup>113</sup>

#### AMINES AND FURFURAL

Meunier<sup>114</sup> obtained a resin by heating equal parts of aniline and furfural in a closed vessel for 48 hours at 70-80°C. or for 3 hours at 140-150°C. The product was soluble in benzene and alcohol. A 15-20 per cent solution of the resin in benzene, applied as a varnish, gives a brilliant black coating. When spread over a surface and heated at 50-60°C. an insoluble black enamel is formed. Enamel formation can be accelerated by adding zinc chloride as a dehydrating agent.<sup>115</sup>

Mains and Phillips<sup>116</sup> made a more extended examination of the conditions under which the resins described by Meunier are formed, and studied the preparation of soluble resins by the condensation of furfural with a number of amines. The method of attack was to determine first the optimum concentrations of amine and furfural for the formation of a resin at room temperature, i.e., approximately 25°C. When no resins were obtainable at this temperature the optimum concentrations were determined at 100°C. Using the concentrations that gave the best results in the previous experiments, resins were made at 25°C., 100°C. and 150-200°C. Having determined the optimum temperature, the length of time necessary under the given conditions to yield the most satisfactory resin was similarly investigated. The resins of course were not pure compounds, but products of indefinite and varying compositions, and substances exhibiting the same consistency were procured over a rather broad range of temperature by

<sup>114</sup> G. Meunier, *Les matières grasses*, 1916, 9, 4516; *Chem. Abs.*, 1916, 10, 2803. Amine-furfural resins are also discussed in Chapter 33.

<sup>115</sup> Cf. G. Meunier, French P. 472,384, 1913; *J.S.C.I.*, 1915, 34, 435.

<sup>116</sup> G. Mains and M. Phillips, *Chem. Met. Eng.*, 1921, 24, 661. U. S. P. 1,441,598, Jan. 9, 1923; *Chem. Abs.*, 1923, 17, 1724.

varying the heating period. The criterion of the quality of the resin was simply that it should be hard and fairly brittle when cooled to room temperature, and yet not be noticeably carbonized. Mains and Phillips<sup>117</sup> confirmed the findings of Beckmann and Dehn that hydrochloric acid is an exceedingly effective catalyst in producing resins from furfural and amines or phenols. It not only catalyzes the formation of both fusible and infusible types of resins, but added to furfural alone effects transformation of the aldehyde into an infusible resin.

The results obtained with each compound follow, all proportions being by weight. Unless otherwise stated, reaction is carried on in an open flask, and the product is hard and brittle at 25°C.

*Aniline.* Equal parts of furfural and aniline heated for 1 hour at 200°C. in an open flask or for 3 hours at 170°C. under a reflux give a black resin.

*Aniline hydrochloride.* Equal parts of furfural and aniline hydrochloride heated at 100°C. for 1 hour produce a black resin.

*Aniline and hydrochloric acid.* Five parts each of furfural and aniline and 1 part of concentrated hydrochloric acid (sp.gr. 1.19) give a resin, similar in characteristics to the above, in 10 minutes at 90°C.

*m-Nitraniline.* By heating 1 part of furfural and 2 parts of m-nitraniline at 150°C. for 1.25 hours, a black resin is obtained. If the temperature exceeds 175°C. a violent reaction occurs, voluminous clouds of dense smoke being evolved.

*Cymidine and hydrochloric acid.* Five parts of furfural, 5 parts of cymidine (1-methyl-2-amido-4-isopropylbenzene) and 1 part of hydrochloric acid (sp.gr. 1.19) heated at 150°C. for 10 minutes give a dark reddish-brown resin. In the absence of hydrochloric acid no resin is formed even after heating for 3 hours at 200°C.

*α-Naphthylamine.* When heated for 3 hours at 200°C., 1 part of furfural and 2 parts of α-naphthylamine condense to form a black resin.

*β-Naphthylamine.* One part of furfural and 2 parts of β-naphthylamine mixed at room temperature (25°C.) immediately form a reddish-brown resin.

*o-Toluidine and hydrochloric acid.* By heating 5 parts of furfural, 10 parts of o-toluidine and 1 part of hydrochloric acid (sp.gr. 1.19) for 1 hour at 150°C. a black resin is produced. Without the addition of the hydrochloric acid no appreciable thickening of the liquid is found even after heating for 3 hours at 200°C.

*p-Toluidine.* One part of furfural and 2 parts of p-toluidine heated for 2.5 hours at 150°C. give a black resin.

*m-Toluylenediamine.* Equal parts of furfural and m-toluylenediamine, upon standing overnight at room temperature, 25°C., give a dark brown resin.

*Xylidine and hydrochloric acid.* By heating 5 parts of furfural, 5 parts of xylidine (crude mixed) and 1 part of hydrochloric acid (sp.gr. 1.19) together for 15 minutes at 150°C., a very thick, dark red, almost black, resin is formed.

*Other amines.* No resins were formed by the action of furfural on amylamine, dimethylaniline, diphenylamine and m-phenylenediamine even after heating at 200°C. for three hours. Furfural condensed with the following at room temperature to form crystalline compounds: p-nitraniline, benzidine and toluidine.

Montgomery and Ernst<sup>118</sup> observed that water solutions of furfural as dilute as 2 per cent, mixed with aniline and heated to 125°C. in an autoclave for 15 minutes, yielded resinous bodies similar to the furfural-aniline resins described by Mains and Phillips. The products, however, give a darker coating when applied to wood. When an excess of aniline is used with furfural solution, the residue is

<sup>117</sup> G. Mains and M. Phillips, *loc. cit.*

<sup>118</sup> J. P. Montgomery and E. S. Ernst, *Chem. Met. Eng.*, 1921, 25, 335.

oily and non-brittle at 25°C.; but on steam-distilling the mixture, unreacted aniline is removed and the residue is hard and brittle at 25°C.<sup>119</sup>

The treatment of dilute solutions of furfural with aniline in the presence of a mineral acid or calcium, iron or zinc chloride at 60°C. gives a resin, melting at 150°C., which is further polymerized by heating under pressure at 180-220°C.<sup>120</sup> Huxham<sup>121</sup> found that the furfural-aniline condensate was applicable as a hardening agent for phenol-aldehyde resins. A solution of the latter in benzene or alcohol, to which furfural-aniline resin has been added, may be employed as a binder for cold-molding compositions and as a varnish or enamel. At a temperature of 150°C. this mixture forms a hard, insoluble product. The proportion of furfural-aniline resin may be as high as 90 parts per 100 parts by weight of the fusible phenol resin. A larger ratio renders the resulting material brittle and weak. In making cold-molding compositions naphtha, chloronaphthalenes, oils or waxes together with asbestos or wood flour may be incorporated.

A resin compatible with cellulose nitrate or acetate is prepared by refluxing equimolecular proportions of p-toluenesulphonamide and furfural with 3 per cent of sodium hydroxide for 8 hours at 150°C.<sup>122</sup> The resin which separates is washed and dried. It is soluble in acetone and alcohol, but insoluble in benzene. Incorporation of this resin with lacquers containing cellulose acetate (as the sole constituent) gives films said to be clear, tough and adherent. The cellulose ester-resin mixture may be worked also into blocks or into sheets that can be used in the preparation of laminated glass. Lacquers may also be produced by dissolving a furfural-aniline condensation product in solutions of cellulose acetate.<sup>123</sup> Addition of furfural and aniline to light-sensitive natural or synthetic resins imparts a black color which masks subsequent color changes of the latter.<sup>124</sup>

Interaction of furfural with the reaction product obtained from stearic acid and aniline forms a waxy material which has been suggested as a plasticizer for moldable phenolic condensates.<sup>125</sup> Another resin similarly used as a plasticizer was prepared by Cherry and Kurath.<sup>126</sup> As an example, 30 parts (by weight) of rosin and 10 parts of aniline are heated together for 3 hours, followed by further heating on the addition of 9 parts of furfural. The product is said to be less brittle than rosin. Economies in the use of materials for making furfural-aniline resins have been effected by distilling the reacting mixture *in vacuo* to recover unreacted constituents.<sup>127</sup>

Beaucourt<sup>128</sup> investigated the condensation of furfural (1 mol) with acid amides (2 mols). Crystalline compounds such as furfurylidene-diacetamide were formed in rather low yield, and in the reaction with formamide only resinous products were obtained. The use of hydrochloric acid or pyridine reduced the yield of the crystalline derivative to nearly one-half.

<sup>119</sup> The preparation of water solutions of furfural is very easy, but its fractionation is somewhat difficult (K. P. Monroe, *Ind. Eng. Chem.*, 1921, 13, 133), and there is always a considerable percentage, frequently up to 8 and 10 per cent, of furfural in the rejected water. If its production is being carried on with a view to subsequent condensation with aniline, it would seem useless to prepare anhydrous furfural. If it is being made for other purposes, the rejected water from fractionation may have enough furfural present to make its recovery as furfural-aniline resin profitable.

## FURFURAMIDE RESINS

Meunier<sup>120</sup> treated furfural with ammonium hydroxide, obtaining furfuramide,  $(C_5H_4O)_nN_3$ ; and then heated the moist product in an autoclave at 120-140°C. for about 3 hours. This procedure gives a brown resin easily soluble in benzene. The benzene solution may be used directly as a varnish, or the resin may be mixed with linseed oil. If ammonium hydrosulphide is substituted for the hydroxide, the resulting substance is a black resin with a disagreeable odor.<sup>130</sup>

Mains and Phillips<sup>131</sup> recommend reacting furfural with ammonium hydroxide and heating the partially dried furfuramide for one hour at 100°C. Trickey, Miner and Brownlee<sup>132</sup> reported that the furfuramide resin of Mains and Phillips was impure furfuralin,  $C_{16}H_{12}O_4N_2$ .<sup>133</sup>

Grinding wheels have been made from a mixture of abrasive grains, gum accroids and a resin derived from furfural and hexamethylenetetramine.<sup>134</sup>

A phenol-formaldehyde-furfuramide condensation product was prepared by Cherry and Kurath<sup>135</sup> by refluxing 200 parts of phenol, 130 parts of formaldehyde and 60 parts of furfuramide until separation into 2 layers had taken place and the odor of formaldehyde was no longer noticeable. The aqueous layer is removed, and the resinous portion is mixed with fillers and molded. Instead of furfuramide, 72 parts of furfural and 30 parts of concentrated aqueous ammonium hydroxide may be used.<sup>136</sup> Hexamethylenetetramine may be substituted for ammonia, in which case the amount of formaldehyde required is reduced. Kurath<sup>137</sup> varied the procedure by first refluxing formaldehyde and phenol with 10 per cent (on the basis of the phenol) of furfuramide. An additional 15-25 per cent of furfuramide is stirred into the mixture and water is removed by decantation. By this method, the possibility of obtaining worthless, rubbery products is reported to be avoided.

As another example of the formation of resins, 200 parts of cresylic acid, 100 parts of furfural and 40 parts of 10 per cent sodium hydroxide solution are refluxed for 4 hours.<sup>138</sup> To the product, 100 parts of formalin are added, and the mixture is boiled for 10 minutes. About 25 parts of furfuramide, sufficient to remove the formaldehyde odor of the composition, are then incorporated. The resulting emulsion may be mixed with fillers, dried and hot-molded. It is essential to keep the proportions of furfural low, if quick-curing products are desired. When relatively larger amounts of furfural are used, however, the reactions may be carried to an advanced stage of condensation, giving materials that still flow well during the molding operation.

<sup>120</sup> G. Meunier, *Les matières grasses*, 1916, 9, 4516; *Chem. Abs.*, 1916, 10, 2805.

<sup>120</sup> A. Cahours (*Ann.*, 1849, 69, 85) obtained thiofurfural by reacting furfural with ammonium sulphide.

<sup>131</sup> G. Mains and H. Phillips, *Chem. Met. Eng.*, 1921, 24, 661.

<sup>132</sup> J. P. Trickey, C. S. Miner and H. J. Brownlee, *Ind. Eng. Chem.*, 1923, 15, 65.

<sup>133</sup> Dubosc (*Le caoutchouc et la gutta-percha*, 1920, 10495; *Kunststoffe*, 1921, 11, 59) found that furfuramide when fused in the absence of air yielded a brown resinous mass consisting for the most part of furfuralin. Bertagnini (*Ann.*, 1853, 88, 128) prepared furfuralin by heating furfuramide at 110-120°C. for one hour, dissolving the resinous mass in alcohol, and precipitating the furfural as the double oxalate. This compound is soluble in boiling water, and is decolorized by treatment with animal charcoal at the boiling temperature, filtered hot, and allowed to crystallize from the filtrate. The furfuralin is liberated by action of potassium hydroxide, and obtained as a white crystalline compound. Furfuralin and formaldehyde give a resin, according to J. Berliner (*Canadian P.* 321,629, 1932, to Canadian Industries, Ltd.; *Chem. Abs.*, 1932, 26, 3392).

<sup>138</sup> O. A. Cherry and F. Kurath, U. S. P. 1,857,357, May 10, 1932, to Economy Fuse & Mfg. Co.; *Chem. Abs.*, 1932, 26, 2885.

## KETONES AND FURFURAL

**Acetone.** Meunier<sup>139</sup> advocated the acetone-furfural reaction for the production of resins useful for industrial purposes. As an illustration of the preparation of this type of resin, 3.5 parts of an alkali solution containing 1 part by weight of potassium or sodium hydroxide and 2.5 parts of water are refluxed, and during the course of 30 minutes, 1 part of a mixture of equal volumes of furfural and acetone is added. The resin formed is washed while hot with dilute hydrochloric acid and dried. One hundred pounds of furfural yield 140-150 pounds of dry yellow resin. A 20 per cent solution in acetone, benzene or a mixture of 23 parts (by volume) of furfural and 77 parts of alcohol serves as a varnish. The original caustic alkali solution may again be used to resinify additional quantities of furfural and acetone.

A harder and more transparent resin may be obtained by another method. To the caustic alkali solution, which is cooled to prevent overheating and volatilization of the ketone, is slowly added a mixture of acetone and furfural. The reaction mass thickens until a hard paste remains. After removing excess alkali, the resin is heated under pressure for 4 hours in an autoclave. By this procedure, Meunier obtained a light-colored transparent resin. A 20 per cent solution of the product (in benzene, acetone or furfural-alcohol mixtures) gives an almost colorless, brilliant varnish. The resin may be heated also with linseed oil to make an oil varnish.

A somewhat similar process using a stronger solution of alkali was employed by Mains and Phillips.<sup>140</sup> Thus, 1 part of furfural, 1 part of acetone and 2 parts of a 50 per cent sodium hydroxide solution are refluxed for 30 minutes at 100°C., forming a dark-brown solid mass. After washing out excess alkali, drying and cooling, a hard, brittle, brown resin is obtained.

Richardson<sup>141</sup> added 150 parts of furfural and 58 parts of acetone to 40 parts of a 15 per cent sodium hydroxide solution at such a rate that the temperature did not rise above 60°C. The alkaline semi-fluid resin is then washed with dilute phosphoric acid, dried at 100°C. and mixed with naphthalene sulphonic acid and non-alkaline fillers. The final condensation is carried out by heat and pressure in a mold. The quality of white resins from the furfural-acetone condensation is improved, according to Routala and Kuula,<sup>142</sup> by replacing part of the acetone with rosin.

Moss<sup>143</sup> prepared lacquers by using an acetone-furfural resin, cellulose acetate, a volatile solvent, a natural resin (such as manila copal), rosin and diethylphthalate. The lacquers yielded clear, hard and adherent films. Incorporation of furfural-acetone resins with phenol-tung oil-formaldehyde condensate to give a varnish or an impregnating agent has also been described.<sup>144</sup>

**Other Ketones.** A mixture containing 5 parts of furfural, 2 parts of methyl ethyl ketone and 5 parts of 50 per cent sodium hydroxide solution gives a dark-brown gummy mass almost immediately at room temperature (25°C.)<sup>145</sup> By washing with dilute acid, drying at 100°C. and cooling, a hard, brown resin is obtained.

Other ketones which may be condensed with furfural include diethyl ketone,

vinylethyl ketone, pinacolone, mesityl oxide, phorone, acetophenone, and the ketone mixture present in acetone oil.<sup>146</sup> Solutions of the resins prepared from these compounds may be used as insulating varnishes.

#### MISCELLANEOUS FURFURAL RESINS

**Furfural and Casein.** Substitutes for ivory and horn or materials suggested as insulators are obtained from casein and furfural.<sup>147</sup> A mixture of 50 parts of finely ground casein and 40 parts of wood flour is thoroughly mixed with a solution of 5 parts of tung oil in 5 parts of furfural. The moist plastic mass is then molded at a pressure of 2500 lb. per square inch and temperature of 100°C. for 30 minutes.

Aluminum caseinate may be substituted for casein in condensations with furfural.<sup>148</sup> The caseinate is prepared by dissolving casein in dilute alkali and adding aluminum acetate and a solution of castile soap. Products made with aluminum caseinate are very similar to the casein-furfural resins and it is said can be employed for the same purposes.

**Polymerized Thiofurfural.** Cahours<sup>149</sup> described a compound prepared by the action of hydrogen sulphide on furfuralamide. At low temperatures the reaction yields a white crystalline powder (thiofurfural), but in hot concentrated solutions of furfuralamide, a resinous body forms. Polymerized thiofurfural can be obtained by leading dry hydrogen sulphide into an alcoholic solution of furfural.<sup>150</sup> After several hours a slightly reddish resinous mass, which contains some impurity having a strong odor, separates from the milky liquid. The resin gradually hardens on standing in a desiccator and is soluble in alcohols and benzene. The molecular weight is about 2000, indicating the combination of approximately 20 molecules of the sulphur-containing furfural.<sup>151</sup>

**Furfural Resins Applied in Photography.** Progress in photography has been so linked with the use of silver halide emulsions that it is somewhat surprising to find light-sensitive synthetic resins applied in this field. Beebe, Murray and Herlinger,<sup>152</sup> however, have realized this possibility with furfural-amine resins. By way of illustrating the method, condensation of furfural and concentrated ammonium hydroxide is effected by gentle heating. The resinous product is washed, dried and dissolved in benzene or acetone. This solution is used to apply a thin film of the resin to the surface on which the photographic print is to be made, and printing is done either by optical projection or by contact, exposing for 1-5 minutes. The image is developed in a 25 per cent solution of benzene in turpentine. The sensitivity may be roughly doubled by adding a small percentage of iodoform, methyl iodide, iodine or ammonium bichromate. If a furfural-acetone resin is used, contact prints may be made in 10 seconds under an arc light. A mixture of furfural and aniline, applied as a thin film to a surface, becomes resinous

<sup>151</sup> E. Baumann and E. Fromm, *Ber.*, 1891, 24, 2591.

<sup>152</sup> Furfural in alcoholic solution cooled to -5°C., acidified with hydrochloric acid and submitted to the prolonged action of a current of hydrogen sulphide yields a crystalline precipitate of two species of trithiofurfural. One melts at 229°C. and the other at 128°C. The latter is quite readily transformed into the species of higher melting point. By the action of ammonium sulphide in absolute alcohol on furfural another polymer is obtained melting at 90°C. which is insoluble in alcohol. On heating it is decomposed into products similar to the preceding. (A. Wurtz, "Dict. de chim. 2nd Suppl.," IV, 394. E. Baumann and E. Fromm, *Ber.*, 1891, 24, 3591; *Bull. Soc. Chim.*, 8, 950).

<sup>153</sup> M. C. Beebe, A. Murray and H. V. Herlinger, U. S. P. 1,537,269, June 1, 1926, to Wadsworth Watch Case Co.; *Chem. Abs.*, 1926, 20, 2292.

after a 5 minute exposure to an arc light. The resin formed on distilling pyrrole is also about as light sensitive as the furfural-aniline mixture.

A condensation product of furfural (10 parts) and  $\beta$ -naphthylamine (15 parts), made at room temperature and dissolved in naphtha to make a 23 per cent solution, also gives a light-sensitive coating.<sup>153</sup> Five grams of iodoform and 0.5 cc. of eugenol are added to 50 cc. of the naphtha solution to act as a sensitizer. Less light-sensitive films are obtained from  $\beta$ -naphthylamine and benzaldehyde.  $\beta$ -Naphthylamine and formaldehyde, cyclohexanone-furfural, m- or p-toluenediamine-furfural, benzidine-furfural, m-phenylenediamine-furfural and xylydine-furfural are other examples of condensates giving light-sensitive materials. The exposure time for the different films varies from 5-20 minutes.

Lithographic plates may be protected from the distintegrating action of the ink used by applying a furfural-acetone coating (insoluble in benzene and acetone) and hardening with heat.<sup>154</sup>

## Chapter 25

### Ketone Resins

Condensation of ketones with themselves or with aldehydes results in the formation of low- and high-boiling liquids (which may be employed as solvents), resins, and colored soluble and insoluble amorphous powders. Compatibility with cellulose derivatives is a characteristic of some ketone-aldehyde resins. Of the aldehydes, formaldehyde is the most active agent of its kind in effecting resin-yielding condensations. Owing to their water-resisting qualities, hardness and toughness, the resins obtained from cyclohexanone and related cyclic ketones are of special interest. Resins derived from that class of bodies of extraordinarily reactive properties—the ketenes—are mentioned also in this chapter. Should cheap methods of manufacturing ketones be developed, these substances could scarcely fail of utilization, not only in resin production but in many other ways. Of the resins described in the present chapter, that one most immediately available is yielded by the reaction between acetone and formaldehyde.

#### ACETONE

This ketone is a colorless, mobile liquid, boiling at 56.5°C. Large quantities of it are used as a commercial solvent. Formerly, acetone was made by the destructive distillation of wood, but the greater proportion now available is obtained by the fermentation of carbohydrate material. Other methods of preparation include catalytic dehydration of acetic acid and catalytic dehydrogenation of isopropyl alcohol.<sup>1</sup> Crude acetone, from the dry distillation of calcium acetate, often contains a less volatile fraction (acetone oil) which consists of pentanones, hexanones, and higher ketones.<sup>2</sup> In the purification of this fraction, the colored bodies are precipitated as non-volatile resinous material by metallic chlorides, such as magnesium or ferric chloride.<sup>3</sup> When acetone is treated with barium hydroxide, two molecules unite to form diacetone alcohol, a liquid boiling at 163-164°C.<sup>4</sup> In the absence of solvents, diacetone alcohol may combine with more acetone to yield sym-triacetone-dialcohol.<sup>5</sup> These keto-alcohols can be dehydrated to mesityl oxide<sup>6</sup> and phorone,<sup>7</sup> respectively. Both these unsaturated ketones, together with resinous products, are obtained by treatment of acetone with sulphuric acid or caustic soda.<sup>8</sup> Reaction

<sup>1</sup> A review of the methods for the preparation of acetone is given by Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., Inc., New York, 1934.

<sup>2</sup> H. Suida and H. Poll, *Z. angew. Chem.*, 1927, 40, 505; *Chem. Abs.*, 1927, 21, 2661.

<sup>8</sup> L. Gmelin, "Handbook of Chemistry," translated by Watts, *Cavendish Society, London*, 1855,

of acetone with methyl ethyl ketone in the presence of hydrogen chloride yields mainly resinous material.<sup>9</sup> Either ketone when heated with hydrogen chloride gives large amounts of brown resin which, according to Herzog and Kreidl,<sup>10</sup> results from the polymerization of mesityl oxide and phorone formed as intermediate products.<sup>11</sup>

Morgan and Hardy<sup>12</sup> heated acetone with 1 per cent caustic soda solution at 180°C. for 3 hours and obtained high-boiling liquids and non-volatile resins. The volatile fraction contained much phorone. Lougovoy<sup>13</sup> used the condensation product, made in the presence of alkali at 100°C., from acetone as a component of paint and varnish removers.

Reduction of phorone in alcohol with sodium amalgam furnishes a viscous oil.<sup>14</sup> By treatment with zinc amalgam and hydrochloric acid, isophorone is converted largely to a resin non-volatile in steam.<sup>15</sup>

### MISCELLANEOUS REACTIONS OF KETONES

Acetone with sulphur or ammonia yields, among other products, a brown resin.<sup>16</sup> Yellow ammonium sulphide in the cold changes it to bis-dithioacetone ( $C_3H_5S_2$ )<sub>2</sub>. Platinum dichloride transforms the ketone into a crude "platinum resin," a dark brown tarry substance.<sup>17</sup> Acetone condenses with pyrrole in the presence of acids,<sup>18</sup> but not of bases,<sup>19</sup> to give an amorphous substance,  $C_{12}H_{10}N_2O$ , and with chloroform and sodium hydroxide to produce a brown sticky mass called chloroacetylulmic acid,<sup>20</sup>  $C_7H_{11}ClO_2$ .

When acetone is mixed with mercuric chloride and dilute aqueous caustic potash and the filtered solution dialyzed, evaporation of the liquid remaining in the dialyzer yields a resinous material whose constitution corresponds to  $2C_3H_6O \cdot 3HgO$ .<sup>21</sup> The same compound is formed by dissolving mercuric oxide in acetone. Solutions of this substance gelatinize on heating or standing. When obtained as a precipitate the particles are gelatinous, but on drying exhibit a resinous nature.

Condensation of acetone with phenyl- $\beta$ -naphthylamine yields a resinous product which can be used as an antioxidant for rubber,<sup>22</sup> and with sulphonated naphthalenes forms wetting agents.<sup>23</sup> Reaction with rape oil and carnauba wax at 90-100°C., in the presence of iron oxide, gives a thick viscous liquid with a high capacity for absorbing water.<sup>24</sup>

Chloroacetone, when treated with potassium hydroxide, is changed to a brown resin.<sup>25</sup> Even on exposure to diffused light it slowly polymerizes to a black rubber-like mass.<sup>26</sup>

### HYDROXY KETONES

Dihydroxyacetone,  $\text{CH}_2\text{OHCOCH}_2\text{OH}$ , is a white material melting at  $82^\circ\text{C}$ . Molecular weight determinations, however, indicate it possesses a bimolecular structure. According to Strain and Dore,<sup>27</sup> x-ray diffraction measurements demonstrate the polymerization of the crystalline monomeric ketone to the dimeric form. Transformation of dihydroxyacetone begins soon after it is prepared and is complete in 25-30 days. From a sample of this ketone which has been stored at ordinary temperatures, Levene and Walti<sup>28</sup> isolated the compounds  $\text{C}_6\text{H}_{10}\text{O}_8$  (m. p.  $164^\circ\text{C}$ .) and  $\text{C}_6\text{H}_8\text{O}_7$  (m. p.  $258^\circ\text{C}$ .) thus indicating that autocondensation (with elimination of water) had occurred. Similar observations were made by Dirschel and Braun<sup>29</sup> with acetoin,  $\text{CH}_3\text{COCHOHCH}_3$ . Monohydroxyacetone (acetol) is reported to polymerize readily but is rendered stable when dissolved in an equal volume of methyl alcohol.<sup>30</sup>

1,2-Dihydroxy-5-hexanone slowly changes to a dimeric form on long standing and when methylated it yields a viscous condensation product.<sup>31</sup> When heated at  $125^\circ\text{C}$ ., in the presence of a small proportion of sulphuric acid, it is converted into a brown resin.<sup>32</sup> Methyl-dihydroxyamyl ketone exhibits similar properties.<sup>33</sup> On boiling diacetone alcohol with solid potash a reddish-brown, easily fusible resin is obtained.

### KETO ACIDS

Pyruvic acid,  $\text{CH}_3\text{COCOOH}$ , is a colorless compound boiling at  $65^\circ\text{C}$ . under 10 mm. pressure. It readily assumes a trimeric form melting at  $92^\circ\text{C}$ .<sup>34</sup> In aqueous solution, the sodium salt of this acid (and also that of laevulinic acid) reacts under pressure at  $230^\circ\text{C}$ . or higher with hydrogen (using an aluminum oxide-nickel catalyst) to give products which, after acidification, resinify quickly in the air.<sup>35</sup> Pyruvic acid and formaldehyde, in alkaline media, furnish trimethylol lactic acid,  $(\text{HOCH}_2)_3\text{CCHOHCOOH}$ .<sup>36</sup> In acid media, a dibasic acid ( $\text{C}_6\text{H}_8\text{O}_8$ ), the alkali and silver salts of which are resinous, and a lactone are obtained.<sup>37</sup> Dehydration of the latter results in the formation of a viscous syrup which changes to a clear hard resin. According to Sen,<sup>38</sup> a saturated solution of potassium hydroxide in ethyl alcohol is the best condensing agent for pyruvic acid and benzaldehyde.

Musajo<sup>39</sup> obtained a vitreous mass when attempting the preparation of a benzilidene derivative of pyruvic acid.

## ALIPHATIC KETONE-ALDEHYDE CONDENSATIONS

**Intermediate Compounds.** The preparation of 3-ketobutanol, or monomethylolacetone, the simplest condensation product from acetone and formaldehyde, is described by Merling and Köhler.<sup>40</sup>

Three kilograms of acetone and 1 kg. of 35 per cent aqueous formaldehyde are condensed in the presence of 20-60 g. of potassium carbonate. When a test portion gives no precipitate after the addition of aniline acetate, the carbonate solution is separated, the mixture is neutralized with acid and filtered to remove the potassium salt. The filtrate is evaporated *in vacuo* at 100°C. and the residue distilled under 30 mm. pressure. 3-Ketobutanol (boiling point 110°C. at 30 mm.) is isolated from the fraction of the distillate which is collected between 95° and 120°C. The residue from the distillation is a very viscous, dark brown liquid. Ketobutanol is a limpid oil, colorless and odorless, miscible with water, alcohol and the usual organic solvents. It polymerizes on long standing to an insoluble viscous syrup, but in the form of its acetate (boiling point 96°C. at 15 mm.) it is quite stable. Methyleneketobutanol is a by-product in the preparation of ketobutanol.<sup>41</sup>

Another procedure is the catalytic dehydrogenation of 1,3-butylene glycol under reduced pressure at 200°C., punice impregnated with a copper compound serving as the catalyst.<sup>42</sup>

Heating ketobutanol with 1 per cent of alkali results in the formation of an infusible resin.<sup>43</sup> This keto-alcohol also reacts with phthalic anhydride at temperatures between 140° and 230°C. to give an orange-colored resin soluble in butyl acetate and compatible with nitrocellulose.

2-Methyl-3-ketobutanol was obtained by Merling and Köhler<sup>44</sup> from methyl ethyl ketone and formaldehyde, following the same procedure as for ketobutanol. Methylketobutanol boils at 90°C. under 18 mm. pressure. This compound does not polymerize as readily as its lower homologue. Reduction of its oxime, followed by heating with a halogen acid, gives 3,4-dimethylcyclobutanimine (3,4-dimethylazetidine).<sup>45</sup>

In the presence of formaldehyde, reaction of 2-methyl-3-ketobutanol with dimethylamine or diethylamine is complicated by further condensation with the aldehyde to yield

and

respectively,<sup>46</sup> two derivatives of therapeutic value.

<sup>46</sup> G. Merling and H. Köhler, German P. 254,714, 1911; *J.S.C.I.*, 1913, 32, 380; German P. 266,656, 1911; U. S. P. 1,070,623, 1,071,007, 1,071,008, Aug. 19, 1918; *J.S.C.I.*, 1913, 32, 925; all patents to Farbenfabr. vorm. F. Bayer & Co.

Claisen<sup>47</sup> observed that alkaline agents, such as potassium carbonate or cyanide, caused acetone and acetaldehyde to combine readily even at room temperature. To the product,  $\text{CH}_3\text{CHOHCH}_2\text{COCH}_3$ , he gave the name hydracetylacetone. This compound (also called methyl acetonyl carbinol) has a ketonic odor and the consistency of glycol. It mixes with water in all proportions and boils at  $77-78^\circ\text{C}$ . under a pressure of 19 mm. To prevent resinification, the alkali should be neutralized before removal of unreacted materials by distillation.<sup>48</sup>

Condensation of aldehydes with ketones may take place in the absence of water.<sup>49</sup> To the alkaline mixture prepared by adding 20 parts of powdered potassium hydroxide to 1000 parts of acetone, and maintained at a temperature of  $5^\circ\text{C}$ ., are added 300 parts of acetaldehyde over a period of 6 hours. After 30 minutes longer, carbon dioxide is passed into the solution to precipitate potassium carbonate, which is then removed. Unreacted acetone is separated from the mixture by distillation. The residue contains hydracetylacetone and only a very small proportion of resin.

Dimethylol-acetone,  $\text{CH}_3\text{COCH}(\text{CH}_2\text{OH})_2$ , is obtained from 1 mol of formaldehyde and 2 mols of acetone in the presence of aqueous alkali sufficient to yield a pH of not less than 10.<sup>50</sup> Reaction may be carried out in the absence of a condensing agent.<sup>51</sup> A mixture of 8 parts of acetone and 4.2 parts of 30 per cent aqueous formaldehyde are heated at  $100^\circ\text{C}$ . under pressure for 48 hours. Dimethylolacetone is obtained in 76 per cent yield. This compound is not volatile at the above temperature but decomposes at  $180^\circ\text{C}$ . under 16 mm. pressure.

Similar condensations with methyl ethyl ketone also yield a dimethylol com-

pound, which melts at  $62^\circ\text{C}$ . and boils at  $140^\circ\text{C}$ . under 16 mm. pressure.

The above-mentioned dimethylol derivatives, as well as one from cyclohexanone

can be prepared in absence of catalysts by heating the reactants in an autoclave to  $130^\circ\text{C}$ .<sup>52</sup> If dehydrating agents (e.g., phosphoric acid) are present, one molecule of water is removed yielding a volatile unsaturated keto-alcohol.<sup>53</sup> For dimethylol acetone the reaction can be represented as

Dimethylol-acetone has been used for the impregnation of fabrics and is rendered insoluble by passage of the treated fabric over hot rolls.<sup>54</sup>

Morgan and Holmes<sup>55</sup> have described the condensation product of 1 mol of acetone and 4 mols of formaldehyde. It was isolated from the reaction mixture of one mol of acetone and two of formaldehyde, after heating with sodium hydroxide. The resulting solution was evaporated on a water bath and the viscous syrupy residue subjected to vacuum distillation. Only 10 per cent was volatile. The non-volatile portion was a brown resin. On further heating, frothing occurred, and the final product consisted of a voluminous, insoluble, friable mass. The distillate contained 3-ketobutanol and a liquid boiling at 164-165° C. (under 20 mm. pressure) which was postulated as 3,3- (or 3,5-) dimethylol-tetrahydro-4-pyrone,

In marked contrast to acetone, methyl ethyl ketone yielded under the same conditions of condensation mostly volatile products consisting of 2-methyl-3-ketobutyl alcohol, the dimethylol compound (2-aceto-2-methyl-trimethylene glycol) melting at 60°C., and higher-boiling viscous liquids. The latter yielded resins when heated with alcoholic alkali. The mono-, di- and trimethylol compounds obtained from diethyl ketone were accompanied by little or no resinous material.

Anhydro-enneaheptitol is the anhydride (m.p. 156°C.) of the heptahydric alcohol resulting from the reaction of 1 mol of acetone with 6 mols of formaldehyde.<sup>56</sup> It is interesting to note that in the presence of a large proportion of formaldehyde, in addition to the six hydrogen atoms in acetone being substituted by (CH<sub>2</sub>OH) groups, the carbonyl group is reduced. The relation of the alcohol to its anhydride can be represented by

Heating acetone and formaldehyde *in vacuo* below the resinifying temperature gives rise to the formation of colorless, viscous products. They may be used as substitutes for glycerol and as dyeing or printing assistants.<sup>57</sup>

(3-methylol-3,5-dicarbethoxy-2,6-heptandione) on condensing ethyl acetoacetate with formaldehyde. Acetaldehyde yields ethyl  $\alpha$ -ethylolacetoacetate (2-hydroxy-3-carbethoxy-4-pentanone) from which a non-crystalline compound, 4-methyl-3,5-dicarbethoxy-3(1-ethylol)-2,6-heptandione, is obtained by the action of diethylamine at  $-10^{\circ}\text{C}.$ <sup>60</sup>

As a mechanism for the reaction between ketones and aldehydes, Bodendorf and Koralewski<sup>60</sup> suggest that the ketone assumes an enol form which unites with the aldehyde, hydration and dehydration of the latter product yielding the keto-alcohol. These steps can be represented by the following scheme:

**Water-Soluble Products.** Condensation of ketones and aldehydes (chiefly acetone and formaldehyde) yields water-soluble syrups. Stockert and Traxl<sup>61</sup> effected the reaction by using 1 per cent of caustic soda (or more if a diluent was present) at  $15^{\circ}\text{C}.$  To avoid the formation of by-products, smaller amounts of alkali (0.3 per cent initially) were added at 24-hour intervals since it is known that an alkaline catalyst is partly or entirely neutralized in the course of the reaction.

By using disodium phosphate as a condensing agent, Ellis<sup>62</sup> obtained viscous water-soluble syrups which on warming with a small proportion of potassium hydroxide become ivory-colored, rubber-like masses. These can be dried and powdered to yield a whitish substance which chars without melting at  $250\text{--}300^{\circ}\text{C}.$  and is insoluble in the usual organic solvents.<sup>63</sup> When sodium carbonate is the catalyst, a reddish oil separates from the reaction mixture. After it is freed of water, the oil can be dissolved in methyl alcohol and mixed with wood flour and alkaline hardening agents to give a molding composition.<sup>64</sup> In the presence of trisodium phosphate, acetone and formaldehyde give a water-white syrup<sup>65</sup> which may be used in lacquers and varnishes. With 1 mol of acetone to 6 of formaldehyde in alkaline media, a fusible, alcohol-soluble resin is formed.<sup>66</sup>

From acetone, or methyl ethyl ketone, and formaldehyde in alcoholic solution, catalyzed by caustic alkali, Huxham<sup>67</sup> obtained a resin which after heating at  $105^{\circ}\text{C}.$  becomes insoluble in organic solvents and alkali. It may be employed as a protective coating for alkali-storage tanks.

By modifying the conditions of condensation, water-soluble viscous liquids are produced which serve as substitutes for glycerol, for the preparation of "anti-freeze" solutions, for the finishing of textiles, or for the impregnation of paper.<sup>68</sup> For example, Voss<sup>69</sup> prepared a thick, viscous, syrupy, water-soluble liquid (which gave no indication of resinification after being kept for a year) in the following manner: 400 parts of formaldehyde (30 per cent) were mixed with 50 parts of acetaldehyde and 15 parts of acetone and to the mixture were added 12 parts of calcium hydroxide. The temperature was maintained at  $30\text{--}35^{\circ}\text{C}.$  After 12 hours, the alkali was precipitated as the oxalate (with oxalic acid) and water and unchanged aldehyde removed by distillation at  $60\text{--}65^{\circ}\text{C}.$  under reduced pressure.

Morgan and Holmes<sup>70</sup> obtained a colorless water-soluble syrup from equimolecular proportions of acetone and formaldehyde at 25°C. in the presence of barium hydroxide. After all formaldehyde had reacted, any remaining alkali was neutralized with carbon dioxide and acetone and water were removed *in vacuo*. Distillation of the colorless, extremely viscous residue under high vacuum yielded a considerable amount of distillate and a residual yellowish-brown, friable resin. On fractionation, the distillate gave a colorless oil (boiling at 90-110°C. under 16 mm. pressure) which spontaneously polymerized to a hard, clear resin. This solid possessed machinable properties, and was insoluble in organic solvents. Irradiation by a mercury vapor lamp accelerated polymerization. Prior to the fractionation step, halogens or halogen compounds (e.g., iodine or iodine monochloride) may be added to the distillate.<sup>71</sup>

Mannich<sup>72</sup> condensed acetone and diethyl ketone with formaldehyde in the presence of ammonium chloride to obtain resinous material.

**Werner's Resin.** Werner<sup>73</sup> first called attention to acetone resin. He mixed 40 per cent formaldehyde solution with acetone and found that reaction did not occur until alkali was added. The addition of a small amount of caustic potash to the undiluted reactants caused an immediate and violent action with the separation of an orange-red product. When the substances are mixed in 10 per cent aqueous solution, combination proceeds much more slowly, the alkalinity of the liquid diminishing considerably as the reaction progresses. After an hour the condensation product begins to separate, and after 24 hours the reaction is complete. The resulting orange-colored, amorphous powder is freely soluble in alcohol, acetone and glacial acetic acid, from which solutions it is precipitated unchanged by water. It dissolves sparingly in benzene, chloroform or ether. Werner stated that the same compound is produced whether an excess of acetone or of formaldehyde is used.

A yellow precipitate is obtained by adding hydrochloric acid to the alkaline filtrate. The resin and the yellow precipitate from the filtrate had the empirical formula  $C_6H_8O$ . Werner proved, however, that it is not a polymer of methylene acetone.

Müller<sup>74</sup> also noted that the condensation of acetone with formaldehyde did not give the expected methylene-acetone. With a small proportion of alkali as a condensing agent, ketobutanol was formed. Larger amounts of alkali gave an amorphous compound ( $C_8H_{12}O_2$ ).

Seventy-five grams of 40 per cent formaldehyde solution and 60 g. of acetone are poured into a solution of 50 cc. of 30 per cent aqueous caustic soda and 200 cc. of 96 per cent alcohol, and the reaction mixture cooled. After standing for 36 hours, the reddish-brown solution is poured into 2 l. of water. A yield of 50-55 g. of a brown, non-crystallizable mass having an odor like that of hexanone is obtained. It has no sharp melting point and chars above 300°C. The resin is soluble in ethyl and methyl alcohol (to give neutral solutions), in acetone, glacial acetic acid and benzol. It is less soluble in ether and almost insoluble in ligroin, water and dilute caustic alkali solutions.

Müller stated that there are two distinct stages in the formation of this resin:

<sup>70</sup> G. T. Morgan and E. L. Holmes, British P. 404,317, 1932; *Brit. Chem. Abs.* B, 1934, 244.

<sup>71</sup> G. T. Morgan and E. L. Holmes, British P. 408,063, 1934; *Chem. Abs.*, 1934, 27, 5692. See also *British Plastics*, 1933, 4, 431. G. T. Morgan, A State Exp. in Chem. Res.; *Rep. Brit. Ass. Advancement Sci.*, 1933.

<sup>72</sup> C. Mannich, *Arch. Pharm.*, 1917, 255, 261; *Chem. Abs.*, 1918, 12, 684.

<sup>73</sup> E. Werner, *Proc. Chem. Soc.*, 1904, 20, 196; *Chem. Zentr.*, 1905, 1, 221.

<sup>74</sup> A. Müller, *Ber.*, 1921, 54, 1142; *Chem. Abs.*, 1922, 16, 3449.

This, however, assumes that all the acetone takes part in the reaction. Under similar conditions, experience has shown that much acetone still remains after all the formaldehyde has disappeared.

Iodine-containing condensation products of acetone and other ketones with aldehydes have been suggested by Hertkorn<sup>76</sup> to replace iodoform as a disinfecting powder. One procedure for preparing such compounds is as follows: One hundred grams of acetone and 250 g. of formaldehyde are mixed in 2 l. of water. To this, 30-60 g. of alcoholic soda are added; and the mixture is gently heated until spontaneous reaction sets in and the liquid assumes a yellow color. It is cooled and allowed to stand for 2 days with frequent agitation. An orange-yellow flocculent precipitate is formed. Heating to 50°C. at this stage favors the deposition of the orange powder. The horny mass obtained by treating the orange powder with iodine is insoluble in water, fairly soluble in alcohol, ether and amyl acetate, and very soluble in acetone and other ketones. The product is almost insoluble in cold benzene or turpentine, but is partially soluble in hot benzene.

Ketone resins may be used as modifying agents to decrease the luster of rayon.<sup>76</sup> For example, a finely divided insoluble product, from the condensation of 1 mol of acetone and 6 mols of formaldehyde in the presence of aqueous sodium hydroxide, is incorporated with the cellulose solution before extrusion. The polymer obtained from the reaction of benzaldehyde and acetone may be employed similarly.<sup>76a</sup>

**Molding Compositions.** Plauson<sup>77</sup> proposed the following molding composition: One hundred parts of wood flour or mineral powder are mixed with 58 parts of acetone and 100 parts of 30 per cent formaldehyde. Ammonia gas is then introduced with continual agitation under a pressure of 1-3 atmospheres. Reaction is complete in 10-15 minutes. Excess ammonia is removed and water evaporated *in vacuo*. Another composition is made from 30 parts of acetone-soluble rubber resin dissolved in 60 parts of acetone and 100 parts of 40 per cent formaldehyde. This mixture is incorporated in a mixing-drum with 150-250 parts of wood flour and a 10 per cent alcoholic or aqueous solution of caustic soda is added. Reaction is complete in half an hour without resorting to pressure. Alkali and excess acetone are removed by washing followed by evaporation. The dry powder molded at 150 atmospheres and 200°C. gives articles which are inert to alkalis, acids and almost all organic solvents. At a pressure of 200-250 atmospheres, the molded article more nearly resembles natural wood. Methyl ethyl ketone may be used instead of acetone; but although it forms a resin, it is partially converted into a volatile compound immiscible with water. An aromatic ketone such as benzophenone does not resinify readily with formaldehyde and an alkaline condensing agent.

It is suggested also that the condensation product from 6 mols of formaldehyde and 1 mol of acetone, made in the following manner, be employed in molding operations.<sup>78</sup> One hundred parts of 30 per cent formaldehyde solution are mixed with 9-10 parts of acetone, and 15 parts of 33 per cent sodium hydroxide solution are gradually added with vigorous stirring. The mixture must be cooled after addition of the base. Twenty-nine parts of a light yellow, granular solid ( $C_6H_8O_4$ ) separate. After washing it is almost white. It possesses high insulating powers, is burned with difficulty and is insoluble. The product from 3 mols of formaldehyde and 1 mol of acetone (at 30-60°C.) was an oily resin which could be coupled with diazotized p-nitraniline to form a dark yellow oil-soluble dyestuff.<sup>79</sup>

**Condensation Products in Varnishes.** Plauson<sup>80</sup> attempted to obtain oil-soluble compounds (to be used in varnish) by reacting formaldehyde and acetone (or other aldehydes and ketones) with turpentine or terpene hydrocarbons at

200°C. Alkali sulphides, carbonates or perborates were employed as condensing agents. The products were soluble in the various solvents for natural resins. More soluble resins were obtained by adding a small proportion of phenols or of linseed oil to the reactants.

The initial condensation products of formaldehyde and acetone, after polymerization by treatment with urea, aniline, or other organic bases, can be incorporated with pyroxylin to give a coating composition.<sup>81</sup> Refluxing equimolecular mixtures of acetone and aldol, in the presence of alkali, yields a resin which may be fused with rosin to form a coating material.<sup>82</sup> A modification of the latter procedure consists in adding rosin and hydrochloric acid to the ketone-aldol mixture before refluxing. Diacetone alcohol and formaldehyde also react, in alkaline media, to furnish resins which may be employed as components of varnish and lacquers.<sup>83</sup>

### UNSATURATED KETONES

Compounds possessing a double bond in close proximity to a carbonyl group exhibit enhanced reactivity. Those of the type  $\text{RCOCH}=\text{CH}_2$  polymerize spontaneously in the presence of catalysts. Blaise and Maire<sup>84</sup> prepared a series of unsaturated ketones by boiling the corresponding chloroketones with diethylaniline.

Such ketones are mobile, lachrymatory liquids which polymerize, on standing, to elastic odorless substances and react quickly with alkali to form brown resins. They may be prepared also by the reaction of olefins with acetyl chloride, in the presence of aluminum chloride,<sup>85</sup>

and by dehydration of keto-alcohols with zinc chloride.<sup>86</sup> Methyl vinyl ketone is obtained by the hydration of vinyl acetylene with dilute sulphuric acid, using

mercuric sulphate as a catalyst and an oxidizing agent (e.g., ferric sulphate) as a promoter.<sup>87</sup> Ketones in which the ethylenic linkage is farther from the carbonyl group have been produced by passing mixed vapors of unsaturated acids and saturated acid anhydrides over manganese oxide at 300-500°C., oleic acid and acetic anhydride furnishing heptadecenyl methyl ketone.<sup>88</sup>

Transformation of unsaturated ketones to yellow resins, which may be used in varnishes, is effected by agitation with 1 per cent aqueous sodium oleate at

60°C.,<sup>99a</sup> or by heating in the presence of oxygen or oxidizing agents.<sup>99</sup> For example, Bradley<sup>99</sup> resinified methyl-methylene-acetone by bubbling air through it at 80-100°C. On evaporation of solutions of this resin in benzene, or ketones, very tough films were obtained.<sup>99</sup> At its boiling point, 2 molecules of this ketone combine to give 1-octene-3,7-dione,<sup>99</sup> and on heating with dilute acid or alkaline solutions 1-hydroxy-octane-3,7-dione is formed.<sup>99</sup> When kept for several days at 60°C., mixtures of methyl-methylene ketone and diolefins (in the presence of diethyl-aminoethoxy-oleylanilide) yield rubber-like products.<sup>99</sup> Condensations of methylene ketone with styrene,<sup>99</sup> maleic anhydride<sup>99</sup> and stand oil<sup>99</sup> have been reported.

Either methyleneacetone or methyl isopropenyl ketone is used as a low-boiling solvent with cellulose acetate and a compatible synthetic resin (e.g., a sulphonamide resin)<sup>99</sup> to make a lacquer.<sup>99</sup>

By treating polymerized methylene acetone, dissolved in acetone, with formaldehyde (and hydrogen chloride) a resin is obtained which may be employed as the intermediate layer in safety glass.<sup>100</sup> Also, the secondary polymeric alcohol (made by reduction of the polymerized ketone) may be condensed with formaldehyde.<sup>101</sup> n-Butylene acetone, prepared from n-butyraldehyde and acetone in alkaline media, resinifies when heated with alkali but is relatively stable in the presence of 20 per cent sulphuric acid.<sup>102</sup> The isomeric isobutylene-acetones are, however, unstable under the same conditions and when treated with sodium hypobromite they yield tars.<sup>103</sup>

Isopropenyl methyl ketone, prepared by dehydration of  $\beta$ -methylketobutanol ( $\text{CH}_3\text{COCH}(\text{CH}_3)\text{CH}_2\text{OH}$ ) with potassium pyrosulphate or anhydrous oxalic acid and zinc chloride, slowly polymerizes (in an atmosphere of nitrogen) at room temperature.<sup>104</sup> The polyketone is a hard, tough, glass-like mass similar in properties to eu-polystyrene, and is soluble in organic solvents with extreme swelling. It appears to contain 1400 units and its structure is believed to be:

On reduction with hydrogen iodide and phosphorus, the polymer yields the hydrocarbon  $(C_8H_8)_n$  instead of  $(C_8H_{10})_n$ . Apparently cyclization occurs during the latter operation giving

Treatment of the ketone with stannic chloride gives black tarry masses, whereas Florida earth is inactive.

Irradiation of isopropenyl methyl ketone with a mercury-vapor lamp effects transformation to a polymer of 480 units. This substance is much softer than the one containing 1400 units, less swollen by solvents, and can be precipitated as a powder by addition of methyl alcohol to its solution in acetone. At  $100^\circ\text{C}$  isopropenyl methyl ketone isomerizes to the dimeric diketone,

An amorphous glassy mass was obtained by Cox and McElvain<sup>106</sup> on heating 87 g. of benzalmethyl isopropyl ketone,  $(\text{CH}_3)_2\text{CHCOCH}=\text{CHC}_6\text{H}_5$ , with 12 g. of sodium ethoxide.

Furylideneacetone with magnesium methyl iodide or phenyl magnesium bromide yields almost exclusively resinous bodies<sup>106</sup>. Mesityl oxide condenses with acetaldehyde in the presence of aqueous caustic soda,<sup>107</sup> and the product (after removal of the alkali) may be converted into a light-colored, elastic, spirit-soluble resin by heating to  $200^\circ\text{C}$ .

Oleone and hypochlorous acid (in the cold) yield the corresponding chlorohydrin, which reacts with soap to give wax-like products.<sup>108</sup>

Benary, Meyer and Charisius<sup>109</sup> state that although hydroxymethylene ketones (resulting from the condensation of ketones with ethyl formate in the presence of sodium ethoxide) are usually stable, hydroxymethylene-methyl-n-propyl ketone,  $\text{C}_6\text{H}_5\text{COCH}=\text{CHOH}$ , quickly thickens and acquires a red color.

### KETENES

Many attempts have been made to improve the yield of ketene from the pyrolysis of acetone. A variety of catalysts have been employed and yields up to 90 per cent have been reported.<sup>110</sup> Hurd<sup>111</sup> obtained evidence of the formation of methylketene by pyrolysis of both methyl ethyl and diethyl ketones. workers have studied the thermal decomposition of acetic acid,<sup>118</sup> acetic anhydride,<sup>119a</sup> diacetyl and pinacolin.<sup>118</sup> Dreyfus<sup>119a</sup> found that some ketene is formed by the interaction of hydrogen and carbon monoxide at high temperatures. Staudinger and Klever<sup>114</sup> treated bromoacetyl bromide (dissolved in ether or ethyl acetate) with zinc, a current of hydrogen (or other inert gas) being conducted at the same time through the reaction vessel. Water and carbon dioxide must be excluded.

After separation of ketene from the crude products of the pyrolysis of acetic acid there were obtained (1) a fraction rich in acetone, (2) a higher-boiling liquid, which contained dimeric ketene ( $\text{CH}_3\text{COCH}=\text{CO}$ ) and dehydracetic acid, and (3) a residual brown tar.<sup>118</sup> Evaporation of the acetone fraction leaves a resinous film.<sup>118</sup>

Substituted ketenes were prepared by Staudinger<sup>117</sup> and his co-workers by treating diphenylketene with substituted malonic acids and distilling the resulting mixed anhydride. In the case of methylethylketene, reactions for its formation from diphenylketene and methylethyl malonic acid can be represented by:

This method was used in making dimethyl, diethyl, dipropyl, dibenzyl, and allylmethylketene.

The same procedure, however, could not be employed for obtaining ketenes of the allene type.<sup>119</sup> Benzalmalonyl anhydride (from silver benzalmalonate and oxalyl chloride), for example, which on distillation should yield a ketene of the

allene type,  $C_6H_5CH=C=O$ , was an amorphous, hygroscopic material which readily decomposed, even in sealed tubes, to give carbon dioxide and a resinous mass. Allene ketenes probably are not capable of existence.

Hurd and Dull<sup>119</sup> report that polymeric ketenes are produced by the thermal decomposition of substituted amides. Thus, both N-acetylcarbazole and acetylphthalimide yield the dimeric ketene (cyclobutanedione),  $CH_2-CO$ . The trimer of

butylketene was identified as a product of the pyrolysis of caproylphthalimide. Dimers of dimethylketene and diphenylketene were obtained from iso-butyrylphthalimide and diphenylacetylphthalimide, respectively.

The linear structure for dimeric ketene (previously mentioned) is advocated by Johnson and Gross<sup>120</sup> who base their conclusions on the catalytic reduction to n-butyric acid and n-butyric anhydride.

**Polymerization of Ketenes.** According to Staudinger and Kleevers,<sup>121</sup> ketene readily polymerizes to resinous matter, though dissolved in ether (0.5-1.0 per cent solutions) it may be retained unchanged for several days. Formation of resins is accelerated by zinc or ferric chloride, sulphuric acid, and tertiary bases. No reaction occurs with oxygen, or with finely divided sodium or potassium.

Rice and Greenberg,<sup>122</sup> however, report that at room temperature polymerization of gaseous ketene is very slow, appreciable change taking place only after several hours. Although the pure liquid is stable at  $-80^\circ C$ ., transformation is rapid at  $0^\circ C$ . and is complete in about 1.5 hours. When dissolved in a solvent, reaction appears to be trimolecular. Also, there is a wide variation in the rate of polymerization in different solvents, higher values being obtained with solvents of high dielectric constants. Contrary to the results of other investigators, Rice and Greenberg report that, within their experimental error ( $\pm 20$  per cent), reaction is not inhibited by antioxidants (e.g., hydroquinone) or accelerated by acetone peroxide.<sup>123</sup> In anhydrous acetone, at  $20^\circ C$ . less than 10 per cent of the dissolved ketene is changed to diketene.<sup>124</sup>

Energetic heating of benzilic acid with anhydrous sodium carbonate yields a dimeric diphenylketene melting at  $168^\circ C$ . and considered to be 3,3,4,4-tetraphenylcyclobutane-1,2-dione,

The latter yields resinous products with a variety of reagents such as alcoholic potassium hydroxide or cyanide, phosphorus pentachloride, thionyl chloride, or acetic acid.<sup>125</sup>

Ethylbromoketene, a brownish yellow oil boiling at  $-40^\circ C$ . under 0.03 mm. pressure, quickly polymerizes on warming.<sup>126</sup> Dimethylketene reacts with isocyanates, carbon disulphide or carbon oxysulphide to give amorphous addition products of high molecular weights (3000-6000).<sup>127</sup> The latter dissolve in organic solvents yielding colloidal solutions which in many instances, after concentrating,

become very viscous. Dimethylketene also is converted (by trimethylamine) into a hard glassy product, which can be depolymerized on heating. This ketene yields resinous materials with aniline, or with ozone and boiling water. Heated under pressure, it forms non-uniform oily products.<sup>128</sup> Ketenes form peroxides when oxidized, and these decompose to amorphous polymers.<sup>129</sup>

The stability of alkyl ketenes appears to increase with an increase in molecular weight.<sup>130</sup> For example, at 250°C. dimethylketene polymerizes to the extent of 70 per cent in 6 hours, diethylketene 28 per cent in 20 days, and dipropylketene only 9 per cent in 28 days. Dibenzylketene, however, is less stable than the dimethyl compound, and in a few hours is completely changed into diketotetra-benzylcyclobutane. Diallylketene, on the other hand, is much more stable than the dibenzyl derivative as the former substance is polymerized 75 per cent in 5 days.

**Miscellaneous Reactions of Ketenes.** With aluminum chloride as a catalyst, ketene reacts with anisole in carbon disulphide solution forming methoxy-acetophenones and higher ketones.<sup>131</sup> Aromatic hydrocarbons may be substituted for the ether (anisole), the products from naphthalene, for example, being naphthyl methyl ketones and a dark-colored, resinous solid.

In the presence of anhydrous potassium acetate, ketene combines vigorously with benzaldehyde, nitrobenzaldehyde or furfural to give dark, viscous liquids and acid anhydrides.<sup>132</sup> With furylacrylic acid a brown liquid is obtained which polymerizes to a black jelly. Hurd, Sweet and Thomas<sup>133</sup> report that ketene and tertiary alcohols form the corresponding acetates<sup>134</sup> and with the Grignard reagent only sticky gums are secured. At -80°C. combination with isoprene was not observed. At higher temperatures von Euler and Ahlström,<sup>135</sup> however, obtained a viscous oil by this reaction.

Passage of gaseous ketene into pyridine, followed by dilution of the mixture with water, gave only a red resin and dehydracetic acid,<sup>136</sup>

Indications were that ketene does not combine with tertiary bases but merely polymerizes.<sup>137</sup> When the base is dissolved in anhydrous solvents (e.g., ether, ethyl acetate, dioxane, or a low-boiling petroleum distillate) and treated with ketene, a vigorous reaction soon occurs resulting in deposition of the resin and yellow crystals. The latter were apparently of lactone character, having the formula  $\text{C}_{18}\text{H}_{11}\text{O}_8\text{N}$ , and formed by the condensation of 4 mols of ketene and 1 mol of pyridine, with the elimination of 1 mol of water.

In the formation of the colloidal condensation products of dimethylketene with arylcarbimides, the primary complexes, which are probably of open-chain structure, combine to form groups containing 5-10 units of the initial complexes.<sup>128</sup>

Pyrolysis of ketene has been investigated by Williamson.<sup>129</sup> At temperatures of 400-500°C. the initial reaction appeared to be the formation of the dimeric ketene ( $C_4H_4O_2$ ) followed by a slow decomposition. Above 530°C. the gaseous products were carbon monoxide (about 66 per cent), methane (30-35 per cent), and ethylene (1-3 per cent). Also a black deposit (presumably carbon) was always formed. The rates of reaction, however, did not reach their limiting values until the walls of the apparatus had been poisoned by several weeks of use. Probably initial decomposition of ketene is:

which is followed by:

At the temperatures employed, union of two methylene groups to give ethylene appeared to be of minor importance. Muller and Peytral<sup>130</sup> report that at still higher temperatures (e.g., 1150°C.) the proportion of ethylene is greater than that of methane. Also appreciable quantities of hydrogen and acetylene are found in the reaction gases.

#### RESINS FROM ARYL-ALIPHATIC KETONES

Acetophenone,  $C_6H_5COCH_3$ , yields a resin as one of the products when it is decomposed at 270-300°C. in the presence of alumina<sup>131</sup> and when it is electrolytically reduced.<sup>132</sup> The material obtained by the interaction of this ketone, phenol and hexamethylenetetramine has been employed as a binding agent.<sup>133</sup> 5-Pseudocumylacetone (from the destructive distillation of wood) decomposes slowly in the presence of alkali to yield a resin.<sup>134</sup> 1-Keto-tetra-hydrocarbazole gives an oily hydrazone and an oxime which is a glassy mass.<sup>135</sup> The phenylhydrazone of n-propyl phenyl ketone slowly changes to a resinous body on standing.<sup>136</sup>

The hydroxy ketones appear to be much less stable. For example, alkali, acid, or zinc chloride easily resinify p-hydroxybenzophenone.<sup>137</sup> Derivatives of p-methoxyacetophenone yield tarry or resinous materials when treated with acids.<sup>138</sup> Skraup and Guggenheimer<sup>139</sup> studied the effect of temperature on p-anisyl methyl, propyl, and isopropyl ketones. Only at high temperatures (340°C. for the first member of the series and 360°C. for the others) did they undergo loss of water and autocondensation, followed by the rapid occurrence of resinification and carbonization products.

$\alpha$ -Chloroacetophenone and  $\beta$ -chloropropiophenone, when treated with sodium in liquid ammonia, are transformed to hard, chlorine-free resins.<sup>140</sup> Substances of

a resinous nature are obtained by heating di-(bromobenzoyl)-ethanol (an orange-colored solid melting at 102°C.) dissolved in an organic solvent<sup>151</sup> or by bromination of 1,2,5-triphenylpentanedione-1,5,<sup>152</sup>

The dibromide of this diketone gives an intractable resin when treated with potassium acetate.

Tetrabenzoyl ethylene<sup>153</sup> and also dibenzoyl,<sup>154</sup>  $\text{C}_6\text{H}_5\text{CO}-\text{OCC}_6\text{H}_5$ , undergo condensation on exposure to light. About 50 per cent of the latter ketone, in 66 per cent solution in alcohol, is converted into resinous bodies after 12 hours exposure. Cinnamylidene-m-nitroacetophenone, in chloroform solution, is readily transformed in sunlight to a colophony-like substance melting between 65° and 70°C., although cinnamylidene-acetophenone is much less affected under the same conditions. Apparently, in aromatic compounds the nitro (and acetamino) group favors resin-formation.<sup>155</sup> Methoxybenzal-acetophenone<sup>156</sup> and 4,4-di-(hydroxymethyl)-benzophenone<sup>157</sup> are resinified by light. The dichloro compound of the latter, dihydroxy-ketone, (in alcohol solution) and ammonia at 80°C. yielded a polymer in which at least 10 mols were combined.

Reaction of methyl magnesium iodide, or solutions of the Grignard reagent, with phenylacetylnaphthalene,<sup>158</sup>  $\text{C}_{10}\text{H}_7\text{COCH}_2\text{C}_6\text{H}_5$ , or with 2-methyl-9-anthrone,<sup>159</sup>

gives resinous masses.

#### CONDENSATION OF ARYL-ALIPHATIC KETONES WITH ALDEHYDES

Acetophenone and formaldehyde combine, in the presence of ammonium chloride, to give two compounds, monomethylolacetophenone,  $\text{C}_6\text{H}_5\text{COCH}_2\text{CH}_2\text{OH}$ , and trimethylol-bisacetophenone,

The former derivative on dehydration and the latter on steam distillation give an oil (phenyl vinyl ketone,  $\text{C}_6\text{H}_5\text{COCH}=\text{CH}_2$ ) which sets to an extremely hard,

gummy mass in a few days.<sup>100</sup> Substitution of methylamine hydrochloride for ammonium chloride results in the formation of two compounds,  $\alpha, \alpha'$ -bisphenacyl-methylmethylamine,  $(C_6H_5COCH_2CH_2)_2NCH_3$ , and  $\alpha$ -methylaminopropiophenone,  $C_6H_5COCH_2CH_2NHCH_3$ .<sup>101</sup> When dimethylamine hydrochloride is employed as the condensing agent  $\omega$ -dimethylaminopropiophenone hydrochloride is obtained.

The latter compound is easily hydrolyzed (with steam) to dimethylamine and phenyl vinyl ketone. Allen and Bridgess<sup>102</sup> found that addition of alcohol to phenyl vinyl ketone, prepared in this manner, caused the deposition of a white, insoluble mass of polymeric material.

Condensation under alkaline conditions often furnishes resins. For example, acetophenone, formaldehyde and potassium hydroxide yield an infusible, elastic, pale resinous product which is soluble in carbon tetrachloride, acetone, and ethyl acetate.<sup>103</sup> Similar results were obtained with propionylacetone or butyrylacetophenone and salicylic aldehyde<sup>104</sup> (with piperidine), and this same aldehyde and acetylbenzoyl<sup>105</sup> (with aniline). On the other hand, Dufraisse and Demontrignier<sup>106</sup> effected reaction of acetophenone with acetaldehyde by means of sodium ethoxide. The product, after treatment with zinc chloride, gave 2-methylvinyl phenyl ketone ( $C_6H_5COCH=CHCH_3$ , m.p.  $20^\circ C.$ ) which was much more stable than its lower homologue.

4,4'- or 2,4'-Dihydroxybenzophenone condenses with aldehydes, in the presence of hydrochloric acid, forming resinous products which are compatible with cellulose acetate.<sup>107</sup> Polycarboxylic acids of diaryl ketones furnish varnish resins when heated with rosin and glycerol.<sup>108</sup> Reduction of mono- and dimethylantrones results in the production of colored polymers which greatly reduces the yield of bianthrone.<sup>109</sup>

### CYCLIC KETONES

Cyclohexanone, a typical cyclic ketone, boils at  $155^\circ C.$ , is slightly soluble in

water and has an odor similar to peppermint. Although it can be prepared by the dry distillation of calcium pimelate it is usually made by dehydrogenation of cyclohexanol.

Resinification of cyclic ketones has been shown to follow a course similar to that of acetone. For example cyclohexanone, when heated at  $320^\circ C.$  under 30

<sup>109</sup> E. Barnett, *Ber.*, 1932, 65, 1563.

atmospheres pressure with alumina, gives mono- and dicyclohexylidene-cyclohexanones and dodecahydrotriphenylene, the analogues of mesityl oxide, phorone and mesitylene, respectively.<sup>170</sup> The same products were obtained by Cornubert<sup>171</sup> by treating cyclohexanone with sodamide. Cyclohexanone condenses with a methyl alcohol-sulphuric acid mixture to form an oil, which on distillation at 18 mm. pressure was found to contain about 30 per cent of resin.<sup>172</sup> By heating cyclohexanone or its homologues with methyl-alcoholic potassium hydroxide under pressure at about 200°C., a brown, oil-soluble varnish resin is obtained. Cyclohexylidene-cyclohexanone forms an almost colorless resin at 120°C. in the presence of a small quantity of alkaline<sup>173</sup> or acid<sup>174</sup> condensing agents.

Light-colored resins, unaffected by sunlight and unattacked by acids or alkalies, are formed when cyclohexanone is condensed alone or with cyclohexanol by boiling with alcoholic potassium hydroxide.<sup>175</sup> Steam distillation removes uncondensed material; water-washing removes the catalyst. The purified product is a hard, clear resin, soluble in most organic solvents, particularly benzene and oils, and is compatible with cellulose esters and rubber.

Methylcyclohexanone reacts with sorbitol to form an acetal.<sup>176</sup> Finkelstein<sup>177</sup> incorporated a cyclic ketone resin with nitrocellulose of low viscosity in a solvent mixture containing ethyleneglycol methyl ether, ethyleneglycol butyl ether, and ethyl alcohol to make a brushing lacquer.<sup>178</sup>

Cyclopropanone exists as a monomer only in solution; and its hydrate, 1,1-dihydroxycyclopropane, forms resinous polymeric material when an ether solution of it is evaporated in the absence of moisture.<sup>179</sup> Oxidation of cyclopentadecanone yields an open-chain acid, lactones and resinous products.<sup>180</sup>

The elimination of hydrogen bromide from 2-bromo-2-methyl-1-hydrindone (with pyridine) gives 2-methyl-1-indone, a solid melting at 47-47.5°C. and boiling at 99-100°C. at 6 mm. pressure.<sup>181</sup> It polymerizes readily when heated to its boiling temperature (240°C.) at atmospheric pressure, and less quickly on warming with alcoholic sodium or potassium hydroxide. When stored, 2-methyl-1-indone slowly changes to a yellow glassy solid. Similarly, 2-hydrindone slowly undergoes decomposition yielding resinous products.<sup>182</sup> Methylenehydrindone<sup>183</sup> resinifies on standing to either a gelatinous product or a white powder, which is apparently a polymer containing 12 molecules. At temperatures above 400°C., the more complex ketones, camphor and fenchone, undergo pyrolysis and form ill-defined, polymerized, unsaturated compounds.<sup>184</sup>

hydroxide, furnishes brown resinous materials.<sup>185</sup> Sudden polymerization occurs when concentrated acid solutions of reductone are heated above 100°C. The product is viscous and amorphous.<sup>186</sup>

**Condensation of Cyclic Ketones with Aldehydes.** From the condensation of cyclopentanone with a large excess of aqueous formaldehyde in the presence of lime, Mannich and Brose<sup>187</sup> obtained amorphous products. On decreasing the proportion of aldehyde, the tetramethylol derivative was formed. For example, 20 g. of cyclohexanone, 315 g. of 9 per cent aqueous formaldehyde and 10 g. of lime gave 17 g. of tetramethylol-cyclohexanol. Equimolecular proportions of ketone and formaldehyde yielded the monomethylol derivative, a liquid boiling at 114°C. under 16 mm. pressure, unstable to both acids and alkalis. Neither menthone, carvone nor camphor could be condensed with formaldehyde.<sup>188</sup>

Cyclic ketones and aldehydes yield resins when condensed in acid or alkaline media. For example, a transparent and almost odorless and colorless product is obtained by refluxing 100 parts of cyclohexanone, 110 parts of 30 per cent aqueous formaldehyde, and 3 parts of concentrated caustic soda solution.<sup>189</sup> Seydel<sup>190</sup> suggests effecting reaction at higher temperatures (150-200°C.) and under pressure. Incorporation of rosin with cyclohexanone, cresylic acid, and formaldehyde gives a varnish resin.<sup>191</sup>

Norton and Sontag<sup>192</sup> point out that soluble and fusible resins are produced when mild alkalis are employed, and insoluble, infusible resins when strong alkalis are used. Sodium carbonate or borate is suggested as the alkaline condensing agent. The reaction products are said to be light-colored or white, and do not darken on exposure to rays from a mercury arc lamp. For example, 100 parts of cyclopentanone, 125 parts of formalin and 4 parts of sodium borate are refluxed at 100°C. until a syrupy liquid is obtained. The latter can be dehydrated to a permanently fusible resin.

The resins from cyclic ketones are resistant to alkali and to acid and are compatible with cellulose derivatives and rubber. Twiss and Jones<sup>193</sup> treated rubber, cyclohexanone, and formaldehyde (in a solvent) with hydrogen chloride to obtain a material for bonding rubber to metals. Steimmig<sup>194</sup> described the preparation of a brushing lacquer by incorporating a cyclohexanone-phenol-formaldehyde resin with low viscosity nitrocellulose and solvents. Moldable material is secured by reacting cyclohexanone with a partially formed phenol-formaldehyde resin.<sup>195</sup> Dreyfus<sup>196</sup> made resins, which may be used in lacquers, by refluxing cyclohexanone with acetaldehyde in alcoholic caustic soda.

Polymerized cyclohexanone or cyclohexanone-formaldehyde resins may be employed in the manufacture of electrical insulators,<sup>197</sup> or mixed with castor oil and chalk, serve as compounds to seal joint boxes in electrical wiring systems.<sup>198</sup> Pigments may be incorporated with the latter composition.

#### MISCELLANEOUS RESINS

5-Phenyl-3-methylcyclohexanone yields a dibromide which becomes tarry at atmospheric temperature.<sup>199</sup> A similar reaction is observed in the case of dibenzilidene-cyclohexylidenecyclohexanone.<sup>200</sup> Bromine, acetyl chloride and thionyl chloride react with cyclohexanonebenzil to give yellow gums.<sup>201</sup> 1-Phenyl-4-ethylcyclohexane-3,5-dione absorbs oxygen from the air and becomes resinous.<sup>202</sup> When boiled for 36 hours with aqueous potassium hydroxide, cyclohexenylacetone gives a quantity of gummy substances.<sup>203</sup>

By condensation of cyclohexylidene-cyclohexanone and terephthalaldehyde in the presence of alkali, Kunze<sup>204</sup> obtained a bright yellow, amorphous powder which decomposed at high temperatures without melting.

The reaction products of acetone or cyclohexanone with glycerol are said to be soft and pliable and may be used as plasticizers for cellulose ethers or esters.<sup>205</sup> Cyclohexanone and phenol (in benzene solution) in the presence of hydrogen chloride give diphenylol-1,1-cyclohexane which in turn is converted by the halogen acid into a resin melting at 200°C.<sup>206</sup> The cyclic ketone condenses also with polymeric vinyl alcohol<sup>207</sup> and with resorcinol.<sup>208</sup>

Ngaiol, a secondary alcohol obtained by reduction of ngaione ( $C_{15}H_{22}O_3$ , an oxygenated sesquiterpene ketone) completely resinifies at 0°C. when treated with 80 per cent sulphuric acid or 100 per cent formic acid. Complete saturation of ngaiol with hydrogen results in the formation of a colorless, viscous oil. A mixture of ngaiol and potassium hydrogen sulphate heated at 190°C. in an atmosphere of carbon dioxide yields dehydrongiene dioxide which rapidly absorbs oxygen from the air and forms a thick brown oil.<sup>209</sup>

Tropinonemonocarboxylic esters are obtained by the condensation of succinic aldehyde, methylamine and acetoacetic esters. On purification they exhibit the properties of drying oils.<sup>210</sup>

The reaction of aromatic ketones or ethers with acetic anhydride and sulphuric acid yields pyrillium (oxonium) compounds which may be isolated as their salts of perchloric acid.<sup>210a</sup> Acetophenone, for example, gives 2,6-diphenyl-4-methylpyrillium perchlorate,

With mildly alkaline solutions (e.g., sodium acetate) this is converted into the oxonium base, which in turn loses a molecule of water and changes to  $\gamma$ -methylene-pyran. The latter forms a colored quinhydrone-like addition compound with the oxonium base for which the term pyranhydrone has been suggested.

When the pyranhydrone (derived from acetophenone) is heated *in vacuo* at 125°C. a molecule of water is lost and a brownish-black glassy material obtained.

Intensive drying of triquinoyl hydrate,  $C_6O_5 \cdot H_2O$ , at 76°C. results in the formation of a yellowish-brown material which may be regarded as polymeric carbon monoxide,  $(C_6O)_x$ .<sup>211</sup> Benzo- and toluquinones (in alcohol solutions) with phenylhydrazine furnish oily liquids insoluble in water.<sup>212</sup> With quinone and ammonia (in ether) brown, amorphous substances are procured.<sup>213</sup>

#### ARYLIDENE KETONES

Benzaldehyde and an aliphatic ketone yield, in the simplest case, a benzylidene ketone. When the ketone carries two methylene groups adjacent to the carbonyl, a dibenzylidene compound can be formed, which by dehydration is transformed into cyclopentenone derivatives.<sup>214</sup>

<sup>214</sup> H. Ryan and P. J. Cahill, *Proc. Roy. Irish Acad.*, 1924, 36B, 334; *Chem. Abs.*, 1925, 19, 467. H. Ryan and J. J. Lennon, *ibid.*, 1925, 37B, 27; *Chem. Abs.*, 1925, 19, 2934. F. R. Japp and W. Maitland, *J.C.S.*, 1904, 85, 1488. D. Vorländer and K. Hobohm, *Ber.*, 1896, 29, 1352. D. Vorländer, *Ber.*, 1897, 30, 2262.

Of the arylidene derivatives of acetone, monobenzylideneacetone yields a resinous product when heated at 230°C. for 12 hours with sodium phenoxide or ethoxide.<sup>215</sup> Sunlight resinifies dibenzylideneacetone in alcoholic solution. Exposure for several months effected 80 per cent conversion to a white powder melting at 125-135°C. and having an approximate composition of  $(\text{C}_{17}\text{H}_{16}\text{O})_x$ .<sup>216</sup> Other methods for converting dibenzylideneacetone into colored polymers of high molecular weights and high melting points include treatment with concentrated alkaline solutions and heating at 180°C. in a stream of carbon dioxide.<sup>217</sup> The resin from the latter procedure was reddish brown, melting at 85-90°C., was soluble in benzene, chloroform, ether, tetrahydronaphthalene, acetone, ethyl acetate and glacial acetic acid, moderately soluble in turpentine and fatty oils, but insoluble in alcohol and petroleum ether. Lacquers made from it in volatile solvents were of good quality. Efforts to produce the resin by heating the ketone in a solvent boiling at a high temperature (for example, decahydronaphthalene, boiling point 185-195°C.) did not give satisfactory results.<sup>218</sup>

An investigation of the effect of heat on several mono- and di-arylidene ketones showed that the grouping  $-\text{CH}=\text{CHCO}-$  was responsible for resinification; that is, this group is a "resinophore."<sup>219</sup> It was noted also that the rate of reaction was a linear function of the number of double bonds, or olefin linkages, in the molecule. In marked contrast, however, the spontaneous polymerization of methyleneacetone,  $\text{CH}_2=\text{CHCOCH}_3$ , and phenyl vinyl ketone,  $\text{C}_6\text{H}_5\text{COCH}=\text{CH}_2$ , indicates that the grouping  $\text{CH}_2=\text{CHCO}-$  is the more reactive resinophore. Although methyleneacetone,  $(\text{CH}_3)_2\text{CH}_2=\text{CCOCH}_3$ , polymerizes more slowly than methyleneacetone, the isomeric ethylideneacetone,  $\text{CH}_3\text{CH}=\text{CHCOCH}_3$ , is not known to polymerize spontaneously, and mesityl oxide,  $(\text{CH}_3)_2\text{C}=\text{CHCOCH}_3$ , and phorone  $(\text{CH}_3)_2\text{C}=\text{CHCOCH}=\text{C}(\text{CH}_3)_2$ , are equally stable. With this in mind, one does not wonder at the instability of the ketenes,  $\text{CO}=\text{CR}'\text{R}$ .

Kreidl<sup>220</sup> prepared varnish resins by heating compounds of the formula  $\text{R}(\text{CH}=\text{CH})_n\text{COR}''$  or  $\text{R}(\text{CH}=\text{CH})_n\text{CO}(\text{CH}=\text{CH})_m\text{R}'$  (where R and R' are aryl and R'' may be aryl or alkyl and n is 1 or 2) for several hours above their melting point. Dicinnylideneacetone forms a resin melting at 130-145°C.; anisalcinnylideneacetone, 135-140°C.; anisalacetone 50-60°C.; and cinnamylideneacetone 55-70°C. The products are soluble in many of the organic solvents with the exception of petroleum hydrocarbons, slightly soluble in alcohol, and fairly soluble in turpentine and fatty oils. The evaporated solutions yield adherent, durable films, stable to light, air, and water.

Styryl ketones,  $\text{C}_6\text{H}_5\text{CH}=\text{CHCOR}$ , exist in both mono- and dimeric forms.

<sup>220</sup> I. Kreidl, German P. 397,803, 1922; *J.S.C.I.*, 1924, 43, 879B.

The latter are postulated as cyclobutane derivatives of truxillic and truxinic ketones.<sup>221</sup> Alcoholic solutions of phenyl o- and p-methoxystyryl ketones resinify either in sunlight or in the presence of acid.

**Miscellaneous Reactions of Arylidene Ketones.** Styryl methyl ketones readily condense with chloroaldehydes in the presence of sodium ethoxide to give amorphous polymers.<sup>222</sup> In an attempt to prepare m-hydroxystyryl methyl ketone from m-hydroxybenzaldehyde and acetone, McGookin and Sinclair<sup>223</sup> isolated only a dark brown, amorphous substance. Electrolytic reduction of styryl methyl ketone in alcoholic caustic soda solution, with a mercury cathode yielded some resin, and with other cathode materials dimeric substances were obtained.<sup>224</sup>

Exposure to light effects resinification of the double compound of dibenzilidene and stannic chloride, of methyl ketopentadienecarboxylate,<sup>225</sup> and cinnamylideneacetylacetone.<sup>226</sup> Cinnamylideneacetone polymerizes even in the dark in the presence of air but more rapidly under the influence of light. Its dimer is a colorless solid, which by the action of heat forms a resinous trimer.

3,4-Dimethoxy- and 3-methoxy-4-ethoxy-styryl methyl ketones were converted almost completely into resins by heating with piperidine.<sup>227</sup> With an acetone-alcohol solution of 3-methoxy-4-isopropoxy-styryl methyl ketone, reaction occurred even in the cold. The formation of polymers was observed when cinnamic aldehyde combined with either acetone or cyclohexanone in presence of caustic soda.<sup>228</sup>

Benzoyl- and acetylacetones condense with anisaldehyde and m-nitrobenzaldehyde, in the presence of piperidine, to yield resins.<sup>229</sup> In a similar manner, 2-naphthol-1-aldehyde and dibenzylketone form 2-benzylidene-3-phenyl- $\Delta^8$ - $\beta$ -naphthpyran,

In acetone solution this compound polymerizes after several days.<sup>230</sup>

## Chapter 26

### Urea-Formaldehyde Resins. Historical. Theoretical

The two outstanding series of moldable resins are unquestionably phenol-formaldehyde and urea-formaldehyde, for they possess in common many valuable properties denied to any other group of substances. The most distinguishing property is the characteristic ability of these resins to cure rapidly. It has been shown in the previous chapters that the rapid-curing property of the phenol-formaldehyde resins has been the greatest factor in bringing these products into commercial prominence. In the urea-formaldehyde series, resins are obtained which approach phenol-formaldehyde in rapidity of cure and which possess certain other highly desirable properties.

The observation that urea and formaldehyde would unite to form, on drying, a glass-like solid was heralded in years past as a discovery of prime importance. Considerable misapprehension arose to the effect that the clear material made in this way resembles glass in transparency, but is much tougher and more suitable for uses where the fragility of glass comes into question. Actually, urea resin "glass" is soft relative to glass itself, and is easily scratched. Also, because of inadequate water-resistance, the surface becomes dulled upon long exposure to humid conditions. Furthermore, the condensation processes continue to occur after the product has been made, and thus ultimately results in strains, cracks and disfigurements. Although the resins are insensitive to shock fracture, they can hardly be called "unbreakable." Thus, there are some limits to the excellence of the properties of the urea resins.

Fortunately, one of the undesirable properties of the urea resins, namely, their susceptibility to fissure formation, is minimized by the incorporation of substantial amounts of cellulose. A definite chemical affinity exists between the cellulose and the urea condensation product, and the resulting stock is permanent, translucent and strong.

An important advantage which the urea resin molding compositions possess over those of the phenol-formaldehyde type is the relative transparency of the molded goods, which makes possible a brilliancy and depth of color that is not easily obtained by any other thermosetting composition. Pigmentation of refined phenol-formaldehyde resins can result in very good shades, but articles molded from compositions so colored are decidedly opaque.

Not only are the exterior appearances or properties of the urea resins highly attractive, but the method of manufacture, and the nature of the raw materials required, is such as to make possible the production of these resins in enormous quantities. Urea is obtained by reaction between ammonia and carbon dioxide; consequently an almost unlimited supply could be obtained. Likewise, formaldehyde is made from methyl alcohol, and this in turn is a product of the hydrogenation of the oxides of carbon. It is a curious fact, and one which interests and puzzles the layman, that, by means of four gases, ammonia, carbon dioxide, carbon monoxide and hydrogen, it is possible to produce hard, solid materials. This

fact is brought home more emphatically because urea resins have been used to quite a large extent in the production of cups, saucers and other familiar utensils.

The steps by which the gaseous substances are ultimately converted into resins are such as to make possible the manufacture of various products of intermediate state of aggregation. Usually the reaction between urea and formaldehyde is carried out in aqueous solution, and the first result is the production of a hydrophilic colloid, which, on further condensation, becomes a hydrophobe. It is possible to check the condensation at the hydrophilic ("water-soluble") stage, and thus produce adhesives and impregnants. It is also possible to carry out the condensation of urea and formaldehyde in the presence of butyl alcohol, in which case the products are soluble in a wider variety of organic solvents, and consequently are more useful in the preparation of lacquers. ✓

\* Cabinet molded by Remler Co., Ltd.; clock cases by General Electric Co.

The hydrophobe is, of course, ordinarily used for making moldings. In this case, the process of thermosetting resembles that used in the manufacture of molded Bakelite, but there are a few essentials in which the two processes differ. Although a phenolic resin, on curing, undergoes chemical reactions which are substantially unalterable, the products of which probably are broken down only at ignition temperatures, the urea resin plastics, at a temperature between 130° and 140°C., form high-melting products, which, however, undergo a stage of decomposition, accompanied by softening, at a temperature of about 260°C. The property of hardening by chemical reaction at a temperature between 130° and 140° has been utilized in the plastics industry to a considerable extent, and, in the United States, there are several large concerns supplying molding compositions to the industry, the recognized brands being Unyte, Plaskon and Beetle (see Fig. 86).

The nature of the chemical reactions taking place during the condensations, and during the thermal hardening, is extremely complicated, and numerous con-

trols are required in order to establish the conditions necessary for the making of resin which can be converted into molded articles.

### THE MANUFACTURE OF UREA

No discussion of the production of urea would be complete without a mention of Wöhler's<sup>1</sup> classical preparation of this compound by the rearrangement of ammonium cyanate. Pure urea,  $\text{NH}_2\text{—CO—NH}_2$  (see Fig. 87), is a white crystalline substance, melting at  $132.6^\circ\text{C}.$ <sup>2</sup> and soluble in water, moderately soluble in alcohol and slightly soluble in benzene. The world's supply of this chemical is largely controlled by a German company.<sup>3</sup>

The increasing demand for urea of high-grade quality has led to the development of a number of synthetic processes for its technical preparation.<sup>4</sup> A commercial method of synthesis involves the use of by-product gases, carbon dioxide and ammonia.<sup>5</sup>

A mixture of carbon dioxide and ammonia is forced into an autoclave, forming ammonium carbamate,  $\text{NH}_4\text{CO}_2\text{NH}_2$ , which is maintained for 2 hours at the temperature ( $135^\circ\text{C}.$ ) required for its conversion to urea.<sup>6</sup> The reaction mass is then transferred to an apparatus in which it is distilled. A solution of urea is run off from the bottom and the unchanged ammonia and carbon dioxide are recovered at the top and returned to the compressor. To continue the process, more ammonia and carbon dioxide are supplied to the autoclave or an aqueous solution of ammonium carbamate or ammonium carbonate is added through the top of the apparatus. The urea solution is concentrated by vacuum evaporation or sprayed into a drying chamber, whence the product is obtained as a fine granular material. By saturating liquid ammonia with carbon dioxide, then heating to  $160\text{--}170^\circ\text{C}.$  under 75–80 atmospheres pressure, urea is formed in 40 per cent yield.<sup>7</sup> This yield is not improved by the use of catalysts, and corrosion during the process is considerable, necessitating the use of stainless steel (e.g., Krupp V4A) for the construction of the autoclave.<sup>8</sup> From a mixture of ammonia and carbon dioxide (molecular proportions, 2 to 1) at  $195^\circ\text{C}.$  and 230 atmospheres, a 47 per cent yield of urea was obtained in 30 minutes,<sup>9</sup> whereas using 10–15 per cent excess ammonia and heating at  $175\text{--}185^\circ\text{C}.$  at 150–175 atmospheres for 0.8–1.5 hours gave rise to a 50–60 per cent yield.<sup>10</sup>

Another process, utilizing synthetic ammonia made from gas mixtures of carbon dioxide, nitrogen and hydrogen is that of Hetherington and Krase.<sup>11</sup> The carbon dioxide is separated by absorption in a solution of an ammonium salt, and the nitrogen and hydrogen are combined to form ammonia, which is then reacted with the recovered carbon dioxide. Liquid ammonia and liquid carbon dioxide are delivered at

<sup>1</sup> F. Wöhler, *Pogg. Ann.*, 1828, 12, 253.

<sup>2</sup> Above its melting point urea dissociates into ammonia. B. H. Reeves (U. S. P. 1,982,539, Nov. 27, 1934, to Rockbestos Products Corp.; *Chem. Abs.*, 1935, 29, 527) treated an electrical conductor with a covering consisting of asbestos containing urea. On heating ammonia is evolved which serves as an arc-extinguishing agent.

<sup>10</sup> B. A. Bolotov and A. N. Popova, *J. Chem. Ind. (Moscow)*, 1934, 9, 32; *Chem. Abs.*, 1935, 29, 457.

<sup>11</sup> H. C. Hetherington and H. J. Krase, U. S. P. 1,780,208, Oct. 1, 1929, to A. B. Lamb; *Chem. Abs.*, 1929, 23, 5476.

controlled rates into a lead-lined jacketed autoclave, which is heated to  $150^{\circ}\text{C}.$ , the pressure rising to 100-110 atmospheres.<sup>12</sup> A maximum conversion of 35-50 per cent is attained, after which unchanged ammonium carbamate is decomposed to recover its component gases, urea solution being discharged from the still (see Figs. 88 and 89). The gaseous mixture on which the process operates is obtained by the catalytic oxidation with steam of a semi-water gas produced by the action of air and steam on hot coke.<sup>13</sup> Ammonium nitrate or chloride is used as the absorbent for carbon dioxide.

Pure urea may be obtained from the technical product by the treatment of concentrated, slightly ammoniacal solutions with oxidizing agents,<sup>14</sup> e.g., air, oxygen or manganese dioxide. Heavy metals are thereby precipitated, and pure colorless urea can be crystallized from the solution. Alternatively, the concentrated solu-

FIG. 87.—50,000,000 Pounds of Urea.

tion containing about 70 per cent of urea and 1.5 per cent of ammonia obtained directly from the synthesis is treated with a fine spray of air at  $70-75^{\circ}\text{C}.$  to give the pure compound.<sup>15</sup>

A further modification of the urea synthesis consists in heating a dry liquefied mixture of carbon dioxide and ammonia to  $80-120^{\circ}\text{C}.$ <sup>16</sup> Carbon dioxide may be replaced by carbon oxysulphide, forming ammonium thiocarbamate which may be converted into urea.<sup>17</sup> For example, 5 parts of ammonia are liquefied in a steel autoclave, and 2.6 parts of carbon oxysulphide introduced. The mixture is heated to  $120^{\circ}\text{C}.$  for 2 hours, at which time the pressure, created by the hydrogen sulphide formed in the reaction, reaches about 18 atmospheres. The contents are extracted with water, and filtered from any impurities (usually iron sulphide from the walls of the container) giving a 70-80 per cent yield of urea. Urea can be prepared in

<sup>12</sup> H. J. Krase, V. L. Gaddy and K. G. Clark, *Ind. Eng. Chem.*, 1930, 22, 289. K. G. Clark, V. L. Gaddy and C. E. Rist, *ibid.*, 1933, 25, 1092.

96 per cent yield by the oxidation of uric acid with chromic-sulphuric acid mixture.<sup>18</sup>

According to Hofsäsz,<sup>19</sup> improved thermal economy and convenience of working in the conversion of ammonium carbamate to urea are attained by compressing carbon dioxide and ammonia with a viscous oil to form a paste containing up to 50 per cent of ammonium carbamate. This is pumped into a chamber at 150-200°C., the pressure being 100 atmospheres, where 40 per cent conversion to urea occurs. Removal of carbon dioxide and ammonia by distillation leaves a solution

FIG. 88.—Flow Diagram for a Direct Synthetic Urea Process. (H. J. Krase, V. L. Gaddy and K. G. Clark.)

of urea and a layer of oil which is returned to the autoclave. Barsky and Griffith<sup>20</sup> obtained urea from cyanamide by adjusting the acidity of the cyanamide solution to 0.1 N and heating at 60°C. Substantially all of the cyanamide is converted to urea under these conditions.

### THE CHEMISTRY OF THE UREA SYSTEM

Empirical observation played an important part in the early development of urea resins. The chemistry of the processes involved had not been worked out, and it is only as a result of more recent work that much information concerning the course of the various reactions occurring, and the structures of the polymerized products, has been obtained. The condensation is conditioned by a certain

number of possibilities in the case of simple molecules portends great complications when highly condensed molecules of urea resin are to be considered. Ammonia and cyanic (or isocyanic) acid enter into reversible combination in two ways

Blair<sup>22</sup> has suggested that in aqueous solution hydrated forms of urea may exist, and accordingly the dearrangement may be formulated as follows:

<sup>21</sup> T. L. Davis, *Proc. Nat. Acad. Sci.*, 1925, 11, 68.

<sup>22</sup> J. S. Blair, *J.A.C.S.*, 1926, 48, 87.

The representation of the preceding compounds as ammonocarbonic acids is supported by the preparation of such salts as potassium-urea ( $K_2H_5CON_3$ ) in liquid ammonia solution.<sup>56</sup> The action of water is usually to effect complete hydrolysis to carbamate or carbonate, but by the use of anhydrous ethyl alcohol, various intermediate stages have been isolated.<sup>57</sup> Thus biuret is progressively alcoholized to ethyl allophanate and urethan:

By the addition of alcohol to the nitrile group of cyanamide, derivatives of the isoureas are formed<sup>58</sup> as indicated in the following equation:

However, the n-propyl and n-butyl isoureas, obtained in a similar manner, form semi-solid uncrystallizable masses.

Substituted isoureas react with diketones and ketonic esters,<sup>59</sup> and in some cases cyclic products are formed, as in the condensation of ethyl isocarbamide and acetylacetone:

Ethyl acetopyruvate ( $\text{CH}_3-\text{CO}-\text{CH}_2-\text{CO}-\text{CO}-\text{OC}_2\text{H}_5$ ) undergoes vigorous condensation to yield, however, an ill-defined gummy product. This tendency is also encountered with ethyl oxaloacetate

In the latter case there is evidence that the presence of impurities favors the formation of amorphous, probably high molecular, products.

The manner in which stable cyclic structures tend to be formed from the mobile urea system is shown by the condensation of isoureas with malonic ester, whereby barbituric acid derivatives are formed.<sup>60</sup>

Reactions essentially similar to those of urea take place with guanidine. Dicyanodiamide can dearrange in two senses,<sup>61</sup> and when heated above its melting point yields the products, ammonia, cyanamide, melamine and melon, the latter two compounds being trimers of cyanamide and dicyanimide, respectively.

<sup>60</sup> S. Basterfield and E. C. Powell, *Can. J. Research*, 1929, 1, 281; *Chem. Abs.*, 1930, 24, 1356.

<sup>61</sup> T. L. Davis, *loc. cit.*

Melamine and melon contain six-membered rings of alternating carbon and nitrogen atoms. The tendency for such rings to form is illustrated<sup>23</sup> by the following reactions in the guanidine series:

Substituted (aryl) guanidines may be prepared<sup>24</sup> by the action of amines upon methyl isothiurea sulphate, and dicyanodiamide may be condensed with o-amino phenol<sup>25</sup> to yield a benzoxazole guanidine derivative. The substituted guanidines and ureas undergo rearrangements paralleling those of the parent compounds,<sup>26</sup> and the fission products polymerize in a corresponding manner. Thus, if in the

dearrangement scheme we replace carbodiimide,  $\text{HN}=\text{C}=\text{NH}$ , by diphenylcarbodiimide,  $\text{C}_6\text{H}_5-\text{N}=\text{C}=\text{N}-\text{C}_6\text{H}_5$ , the crystalline trimer<sup>36</sup> of that substance takes the place occupied by melamine. Instead of combining with itself to form a trimer, diphenylcarbodiimide may unite with a mol of aniline in a manner which also sustains the parallelism,

It is of interest to note that triphenylguanidine, when heated for two hours at  $180^\circ\text{C}$ ., is converted into an amber-colored, brittle, glassy resin. The transformations in the thiourea series are similar to those encountered in the case of urea or guanidine.<sup>37</sup>

#### CONDENSATION OF ALDEHYDES AND KETONES WITH UREA

Amides in general undergo condensation with formaldehyde. In 1892, Pulvermacher<sup>38</sup> observed that in acid solution formaldehyde reacted with benzamide according to the equation,

Einhorn<sup>39</sup> isolated a different crystalline product,  $\text{C}_6\text{H}_5\text{CONHCH}_2\text{OH}$ , which he obtained both in acid and in alkaline solution. With formamide or acetamide, formaldehyde gave colorless syrupy products. The methylol-amide type of structure has since attained great importance in the chemistry of the urea resins. Recent studies<sup>40</sup> have shown that the Pulvermacher structure

is also often formed.

Weber and Tollens<sup>41</sup> observed that uric acid forms a number of "addition compounds" with formaldehyde. Sachs<sup>42</sup> pointed out an analogy between these addition compounds and the product obtained from phthalimide,

Postponing, for the moment, a more detailed discussion of the reaction between urea and formaldehyde, suffice it to say at this point that an important intermediate in the reaction between these two substances is dimethylolurea.

In acid solution, dimethylolurea reacts with benzene derivatives, such as o-nitrophenol, according to the equation:<sup>48</sup>

The related compound methylolbenzamide has been found by Monti<sup>49</sup> to undergo condensation with such representative  $\beta$ -diketones as benzoylacetone. With antipyrine, a condensation takes place in concentrated sulphuric acid to yield a resinous precipitate from which 4-benzoylaminomethyl-1,5-dimethyl-2-phenyl pyrazolone was isolated.

Although urea readily forms methylolurea derivatives with formaldehyde, monochlorourea ( $\text{NH}_2\text{—CO—NHCl}$ ), according to Ottensooser,<sup>48</sup> reacts with aldehydes to form compounds of a different type such as

Two urea residues may be involved in the condensation. For example, the product from propionaldehyde is:

The corresponding compound from isobutylchlorourea was not the final product

<sup>48</sup> H. de Diesbach, O. Wanger and A. von Stockalper, *Helv. Chim. Acta*, 1931, 14, 355; *Brit. Chem. Abs. A*, 1931, 614.

when 5 per cent potassium hydroxide was used as a condensing agent, for ring closure occurred forming

Thiocarbanilide reacts with chloroacetic acid to give isothiohydantoin or diketo-tetrahydrothiazoles depending upon the type of solvent used.<sup>46</sup> The latter compound enters into reaction with aromatic aldehydes as indicated.

Taylor<sup>47</sup> found that ketones and aromatic aldehydes condensed with thiourea in the presence of hydrogen chloride giving sulphur-substituted derivatives, which underwent rearrangement on removal of the acid, forming compounds related to the methylolureas:

<sup>47</sup> J. Taylor, *J.C.S.*, 1922, 121, 2267.

Bromal hydrate condenses with urea forming bromalurea, from which ethers may be obtained.<sup>48</sup> This behavior indicates that the bromalurea possesses the following structure:

Dibromalureas are formed in an analogous manner. Chloral hydrate<sup>49</sup> reacts similarly with tolyl- and nitrophenylureas, giving compounds of the type

Simultaneous condensation of urea with benzaldehyde and ethyl acetoacetate gives ethyl benzuramidocrotonate.<sup>50</sup> Resinous substances were obtained from benzur-

amidocrotonic ester by Biginelli<sup>51</sup> who isolated from the products of sodium-amalgam reduction a glassy solid (m. p. 59-60°C.), which he assumed to be a mixture of two isomeric benzuramidobutyric esters. Condensation of m-nitrobenzaldehyde and acetoacetic ester in equimolecular proportions with urea resulted in the production of an insoluble solid, and a substance deposited from hot alcohol as a jelly-like mass. From urea and cinnamic aldehyde, a cinnamic ureide of reddish color was obtained, resembling porcelain in appearance, to which the following structure was assigned:

#### CHEMISTRY OF THE UREA-FORMALDEHYDE REACTION

The foregoing brief survey of the chemistry of urea may serve to bring out certain points of importance in the interpretation of the structure of the urea-formaldehyde resins and the mechanism of the resinification process. Attention may be drawn especially to the tendency to form methylolureas; the mobility of the carbamide system which enables reaction to proceed from either the urea or the isourea structure; the ease of polymerization, either with or without the elimination of water and ammonia; and finally, the readiness with which cyclic structures are formed in the polymerization process.

The reaction of formaldehyde with urea was early studied by Goldschmidt,<sup>52</sup>

<sup>48</sup> F. D. Chattaway and E. J. F. James, *Proc. Roy. Soc.*, 1932, A137, 481; *Chem. Abs.*, 1932, 26, 5549.

<sup>50</sup> L. H. Hinkel and D. H. Frey, *Rec. trav. chim.*, 1929, 48, 1280; *Chem. Abs.*, 1930, 24, 853.

<sup>51</sup> P. Biginelli, *Gazz. chim. Ital.*, 1893, 23, 366; *J.C.S.*, 1893, 64, 645.

<sup>52</sup> C. Goldschmidt, *Ber.*, 1896, 29, 2438.

who by effecting condensation in neutral, or better in acid, solution obtained a white granular substance which, according to analysis, may be represented by the formula  $C_5H_{10}N_4O_5$ . If the reaction is considered as taking place between 2 mols of urea and 3 of formaldehyde with the elimination of 2 mols of water, then, the resulting compound might possess structures such as

The later work of Dixon<sup>53</sup> indicated that these structures were erroneous. A different substance had already been obtained by Hölzer<sup>54</sup> and Lüdy<sup>55</sup> in the form of methyleneurea,  $C_2H_4N_2O$ . This compound was formulated in two different ways, namely:

Another simple compound which was early isolated<sup>56</sup> from reaction products of urea and formaldehyde in alkaline solution is dimethylolurea. It was noted that this substance gave off formaldehyde on boiling with water or mineral acids. Two crystalline compounds were later prepared by Einhorn<sup>57</sup> who used barium hydroxide as a condensing agent. Investigation showed that these compounds were mono- and dimethylolurea

Methylolurea compounds were first thoroughly investigated by Einhorn and Hamburger.<sup>58</sup> They showed that the composition of the products obtained varied considerably with the conditions of condensation, but that the methylolureas were indeed the first condensation products, and could be isolated if the alkaline condensing agent were neutralized before further reaction occurred. Using barium hydroxide as condensing agent, and neutralizing with carbon dioxide, dimethylolurea,  $\text{CO}(\text{NH}-\text{CH}_2\text{OH})_2$ , was isolated as a crystalline, easily soluble body melting about  $126^\circ\text{C}$ ., but changing at  $137^\circ\text{C}$ . to an amorphous substance decomposing at  $260^\circ\text{C}$ . An insoluble amorphous precipitate was deposited from dimethylolurea solutions by the action of alkalis and to a lesser extent by acids, but no well-defined sub-

<sup>58</sup> A. Einhorn and A. Hamburger, *Ber.*, 1908, 41, 24.

stance of constant composition was observed. Monomethylolurea,  $\text{NH}_2\text{—CO—NH—CH}_2\text{OH}$ , was obtained by using a small proportion of barium hydroxide as condensing agent, and neutralizing with carbon dioxide immediately. The addition of dilute acids produced immediate deposition of a flocculent amorphous precipitate which, as with the previous product, yielded no definite chemical entity.

Scheibler, Trostler and Scholz<sup>80</sup> have investigated the further stages of the condensation, with the result that the preliminary formation of monomethylolurea, when neutral formaldehyde was used, has been confirmed. This when pure, was found to be transformed by a trace of hydrochloric acid into a high-molecular-weight product of the same composition. However the polymer is not considered as consisting of methylolurea units, but rather units of methyleneurea each containing one firmly bound molecule of water:

On the other hand when methylolurea is treated with glacial acetic acid, two well characterized modifications of methyleneurea were obtained. Of the two compounds so produced, one is soluble in glacial acetic acid and contains one mol of acetic acid in combination with an average of 12 mols of methyleneurea, whereas the other contains 1 mol of water in combination with the same number of methyleneurea units and is insoluble in acetic acid.

According to van Laer,<sup>81</sup> the two forms of methyleneurea (vide supra) are in tautomeric equilibrium:

However, when symmetrical dimethylurea was condensed with formaldehyde, a monomethylol derivative was obtained.

No cyclization or polymerization occurs in this case, a fact which could be interpreted as indicating that the ( $\text{N=CH}_2$ ) group is the one which is involved in the polymerization of methyleneurea. Furthermore, the polymerization of methyleneurea may then be readily conceived as a process analogous to that which takes place in the formation of polyoxymethylene<sup>81</sup> long-chain molecules: e.g.,

<sup>80</sup> H. Scheibler, F. Trostler and E. Scholz, *Z. angew. Chem.*, 1928, 41, 1305; *Chem. Abs.*, 1929, 23, 2425.

<sup>81</sup> M. van Laer, *Bull. soc. chim. Belg.*, 1919, 28, 381; *Chem. Abs.*, 1922, 16, 2113.

<sup>82</sup> H. Staudinger, *Ber.*, 1926, 59, 3019.

From this formula it may be seen how a molecule of acetic acid or a molecule of water might add on to the free valencies at the end of the chains, forming the acetic-acid-soluble and insoluble compounds already mentioned.

In a similar manner, halogens may add on to the polymethyleneurea chains. Such substances, formed in glacial acetic acid solutions, according to Scheibler, Trostler and Scholz,<sup>22</sup> are not very stable, but give up their halogen on standing in the air, or on slight warming. The *loose* bromine compound formed in this way contains too little bromine to be a bromamine or bromamide, but corresponds to the bromine addition compound of a trimeric methyleneurea:

Starting with two mols of formaldehyde to one mol of urea, the known dimethylolurea constitutes the initial product, but readily splits off formaldehyde on standing, with formation of the polymerized methyleneurea previously described:

Insoluble compounds are not obtained when dimethylolurea is dissolved in cold acetic acid, but upon addition of an acetic acid solution of bromine, a bromine addition product precipitates. Analysis for bromine indicates that this compound contains 3 dimethyleneurea residues.

A trimeric crystalline methylolmethylenurea, combined with one molecule of water, is produced by condensation of two molecules of formaldehyde with one mol of urea in the presence of a little ammonia, and corresponds exactly with the bromide described. In contradistinction to the well-defined compounds here discussed, the use of caustic alkalis as condensing agents has been found to lead to products of variable composition.

In addition to following the successive steps of the condensation process, Scheibler and co-workers studied the degradation of the synthetic resinous mass. By prolonged boiling with glacial acetic acid, the substance is dissolved completely, and addition of absolute alcohol then precipitates a white amorphous substance which is soluble in cold water. Formaldehyde and methylamine are evolved in the solution step, the latter being found only in the presence of a little water. The origin of methylamine may be attributed to the separation of a  $(-\text{N}-\text{CH}_2-)$  group by hydrolytic fission, which is then reduced by formaldehyde. The degrada-

<sup>22</sup> H. Scheibler, F. Trostler and E. Scholz, *loc. cit.*

tion product may be acetylated with acetic anhydride to give acetyl derivatives which, in turn, yield bromine addition compounds resembling those obtained synthetically and described above. Therefore, degradation evidently yields a polymeric methylene- or methylolmethyleurea.

The conception of the polymerized mass afforded by the study of the degradation is that of chains of dimethyleneurea or methylolmethyleurea units joined together, the free ends of the chains being attached to water molecules. Such chains may be associated by secondary valence forces into micelles and colloid particles, conferring on the polymerized material its characteristically high-molecular physical properties. Degradation leads to replacement of the terminal water molecules by acetic acid, or bromine, with possibly a simultaneous shortening of the mean chain length.

It is to be noted that the polydimethyleneurea products cannot be hydrogenated, and so do not in reality contain the azomethane grouping implied by the formulation

It is believed, therefore, that saturation is possibly achieved by a process of ring formation, according to the general scheme:

Walter and Oesterreich<sup>28</sup> have applied an interesting method to the study of the condensation process, by utilizing the ability of thiocarbamide to enter into complex compound formation with metal salts. Thus, with cuprous chloride, thiourea forms the stable complex

The complex salt, in turn, undergoes reaction with formaldehyde to yield colloidal solutions from which flocculent precipitates may be obtained upon addition of potassium chloride. These precipitates differ from those obtained in the urea-formaldehyde condensation, in that they may readily be dried for analysis. Such complex salts offer the additional advantage that the copper and chlorine content permit of less ambiguous analysis than is possible with dried urea-formaldehyde products. This last-named fact, coupled with cryoscopic measurements, enables some evidence to be obtained as to the complexity of the condensed system. Yellow viscous solutions with identical properties were obtained first by the action of formaldehyde (6 mols) on the cuprous chloride complex mentioned above; secondly, by the simultaneous reaction of equivalent amounts of thiourea, formaldehyde and cuprous chloride; and thirdly by the action of dimethylolthiourea on cuprous chloride. Evaporation of the solution obtained by the first method afforded a resin of the approximate composition

<sup>28</sup> G. Walter and K. Oesterreich, *Kolloid-Beihfte*, 1931, 34, 115; *Chem. Abs.*, 1932, 26, 3682. G. Walter and H. Lutwak, *Kolloid-Beihfte*, 1934, 40, 158; *Chem. Abs.*, 1935, 29, 5198.

The second reaction, involving the action of both methylol- and dimethylolthiourea on cuprous chloride, yielded a substance approximating

which upon polymerization by heat, gives a product of lower copper content. The identity of the products from the mono- and dimethylolureas is attributed to the initial formation of dicyclic structures:

Such structures are, then, coordinatively linked to the copper through the secondary nitrogen atoms. The cryoscopic investigation of solutions of dimethylolurea, with and without addition of cuprous chloride, indicated that mild polymerization led only to an increase in the proportion of dicyclic polymers as compared with straight-chain polymers. Prolonged heating led to loss of formaldehyde and water, and Walter considered that the resins formed were probably represented by a tetracyclic structure.

The conclusion drawn by Walter<sup>64</sup> from the evidence of this work is that a relatively low molecular weight must be assigned to the urea-formaldehyde resins, the resinous properties being attributable, presumably, to colloidal association.

According to Dixon,<sup>65</sup> dimethylolurea loses water and formaldehyde, when heated above its melting point, to yield a compound which appears to be identical with Goldschmidt's product, discussed earlier in this section.<sup>66</sup>

By using a trace of sodium acetate as a condensing agent and neutralizing as soon as fusion occurs, typical glassy resinous end products were obtained.

Evidence for the formation of ramified chains and cyclic structures in the urea-formaldehyde condensation has been obtained by Walter and Gewing<sup>67</sup> from the analytical study of the water and formaldehyde lost during the process. If the molar ratio

$$\frac{\text{water lost}}{\text{urea in substance}}$$

<sup>64</sup> G. Walter, *Kolloid-Z.*, 1931, 57, 229; *Chem. Abs.*, 1932, 26, 4486. See also R. Houwink, *British Plastics Year Book*, 1935, 51.

<sup>65</sup> A. E. Dixon, *J.C.S.*, 1918, 113, 238.

<sup>66</sup> C. Goldschmidt, *Ber.*, 1896, 29, 2438.

<sup>67</sup> G. Walter and M. Gewing, *Kolloid-Beihfte*, 1931, 34, 163; *Chem. Abs.*, 1933, 26, 3941.

be denoted by  $W$ , and the molar ratio

$$\frac{\text{formaldehyde lost}}{\text{urea in substance}}$$

by  $F$ , it can readily be seen from previous considerations that the condensation of dimethylolurea units to form Goldschmidt's compound would yield the following values:

$$\begin{aligned} W &= 1 \\ F &= 0.5 \end{aligned}$$

Actually, Walter and Gewing found that dimethylolurea condensed with itself in the absence of catalysts in such a way as to give 1.007 mols of water and 0.4992 mol of formaldehyde, which confirmed the work of Dixon.

However, in the presence of condensing agents, the experimental values for  $W$  and  $F$  were no longer in such a simple ratio.  $W$  varied from 1.31 to 1.86, and  $F$  varied from 0.15 to 0.47. Therefore, some further reaction involving the splitting out of more water and less formaldehyde must have taken place.

Additional information was provided by a determination of the number of methylene and also the number of methylol groups per urea residue. It is obvious that the number of methylene or methylol groups must be equal to twice the number of urea residues minus the number of escaped formaldehyde molecules.

If  $N$  indicates the number of urea residues per mol of condensation product,  $W$  the escaped water (per urea residue),  $F$  the escaped formaldehyde (per urea residue),  $M$  the methylol groups (per urea residue), then it is generally true that  $W = 2 - (M + F)$ . Furthermore, by allowing  $m$  to represent the number of formaldehyde groups per molecule of resin which have not been converted to methylene groups, (i.e., all the formaldehyde in the resin, including free formaldehyde and that bound as methylol groups),

$$m = N(M + F)$$

$$\text{It follows algebraically, } W = \frac{2N - m}{N}$$

For an open chain structure of the type

$$\begin{aligned} m &= N + 1 \\ \text{and } W &= \frac{N - 1}{N} \end{aligned}$$

Thus, in considering the limiting case where  $N$  is very large,

$$W = 1$$

This value is incompatible with the analytical data of Walter and Gewing, hence a simple open chain structure is excluded.

In the case of an open ring chain structure, such as

$$m = 2$$

$$\text{and } W = \frac{2N - 2}{N}$$

it can readily be seen that the limiting value for  $W$  in this case is 2. Such a structure for the urea-formaldehyde resins is, therefore, possible provided  $N$  is not excessively large. A variant in which one methylol group is eliminated as formaldehyde leaving the terminal structure in the following form is also possible.

The experimentally determined values of  $W$ , and also the physical properties of the resins, suggest that such a simple ring chain does not completely represent the structure of the high-molecular substances involved. Formulas with ramified chains, however, are more readily compatible both with the quantitative data and the nature of the resinous products. A structure such as the following may be looked upon as being derived from Goldschmidt's compound and formaldehyde.

In the formation of Goldschmidt's compound from two dimethylolurea molecules, one formaldehyde molecule is split out. If this formaldehyde is taken up again in the formation of the ramified chain, the net change of formaldehyde would be zero. From the structure given above,

$$M = \frac{N}{2} + 1 \qquad W = \frac{3N - 2}{2N}$$

with the result that  $W$  tends to approach a limit of  $3/2$ . This concept agrees fairly well with the experimentally determined values of  $W$  and  $F$ , already referred to above.

The formation of rings larger than the eight-membered ring hitherto considered is also possible:

$$M = \frac{N}{2} + 2$$

$$W = \frac{3N - 4}{2N}$$

$$\text{Limit of } W = 3/2$$

Numerous minor variants of the two preceding types might also be formed, all giving a value for  $W$  in the neighborhood of the values found by experiment. Although the simple chain and ring chain structures are capable of only unidirectional growth, forming linear molecules, the more complex schemes enable condensation to proceed progressively, the methylol groups condensing with the remaining secondary nitrogen atoms of contiguous molecules until the whole becomes knit in a vast ramification of fortuitously arranged three-dimensional networks. The conception may be compared with that holding good for the three-directional ramified, heat-convertible glycerol phthalates (Chapter 41). The values of  $N$  determined by Walter and Gewing were, however, lower than anticipated, the highest value being about 20.

The theory of Walter and Gewing discussed above probably affords a fair representation of the general lines upon which the condensation proceeds, but is not entirely satisfactory. In particular, the nitrogen content of a resin of type (I) would be 30.0 per cent, whereas that of the actual urea-formaldehyde resin, according to Dixon<sup>20</sup> is 32.8 per cent.

If the polymerization be considered as proceeding through the methylolureas, the possible product, starting with monomethylolurea, will be either *A* or *B*, according as the primary or secondary amido-nitrogen is the more reactive.

The mixed type *C* is also possible if both nitrogen atoms participate equally in the polymerization.

If, on the other hand, polymerization proceeds through initial loss of water leading to the formation of methyleneurea, the product could only be of the type *B*:

<sup>20</sup> A. E. Dixon, *loc. cit.*

In the case of dimethylolurea, the nature of the products and general considerations indicate that the conditions are essentially similar. Chain formation in this case may be conceived as taking place in two possible ways to yield *D* and *E*,

or possibly mixed types as before. Since branching may occur at every methylol group, the formation of long straight chain polymers is improbable. If, now, the remaining methylol groups eliminate water giving methylene groups, *F*, a redistribution of valencies gives the double chain *G*

The chain *D* contains 27.4 per cent nitrogen, whereas *F* and *G* contain 33.3 per cent which compares favorably with the value 32.8 per cent found by Dixon.

As has been stated, in the actual condensation process chain branching is inevitable, so that the cured resin, if perfectly oriented, could be represented in the simplest case by the formula:

The outer unsaturated valencies would be attached, in the case of the nitrogen atoms to hydrogen, and in the case of methylene groups, to hydroxyl. It may be that the acid or basic radicals of catalysts or fillers are chemically attached to these bonds.

De Chesne<sup>22</sup> arrived at a similar mechanism for the condensation of urea and formaldehyde. His views are based chiefly on the work of Scheibler and Walter, but he has concluded rather that the ultimate product consists of linear polymeric molecules possessing one-dimensional extension only, after the type of the polyoxymethylenes. The first stage of the condensation is regarded as an addition process, the products of addition being mono- and dimethylolurea, which may be isolated by checking the subsequent process of polymerization. A further intermediate step was represented by a crystalline soluble substance melting at 156°C., which cannot, however, have been homogeneous since de Chesne found it to have a variable composition. At every stage beyond the initial formation of dimethylolurea, the condensed mass consists invariably of the complex mixture of ill-characterized, non-separable substances representing a variety of stages in a progressive polymerization process.

The oxidative degradation of the resin at various stages of the polymerization, using a mixture of concentrated nitric acid and 40 per cent hydrogen peroxide led to the formation of soluble products, from which a crystalline compound was isolated by de Chesne. Analysis of this product indicated the formula,  $C_6H_{12}O_6N_4$ ; hence, it would seem to be a dimethylolurea peroxide having the probable structure

and is apparently identical with that obtained by Girsewald and Siegens<sup>23</sup> who employed peroxide oxidation during the condensation of urea and formaldehyde. The oxidative degradation of urea-formaldehyde resin evidently effects a complete decomposition to give the starting materials.

Examination of numerous high-molecular substances by the methods of x-ray crystallography has shown them to possess a microcrystalline structure, but in the present instance de Chesne found urea-formaldehyde resin to be completely amorphous.

The mechanism of polymerization envisaged by de Chesne is the preliminary formation of methylolurea, or if the  $p_H$  of the reaction mixture be greater than 7, dimethylolurea. Methylolurea then undergoes linear condensation with elimination of water:

Dimethylolurea, in the alkaline reaction mixtures, condenses to the same product, formaldehyde and water being split out simultaneously:

<sup>22</sup> E. B. de Chesne, *Kolloid-Beihfte*, 1932, 36, 387; *Chem. Abs.*, 1933, 27, 459.

<sup>23</sup> C. von Girsewald and H. Siegens, *Ber.*, 1914, 47, 2467.

The intermediate stages of the polymerization form highly viscous solutions, which according to de Chesne, display the properties of a highly solvated micelle-colloid. Thus, the high viscosity of the solutions is diminished greatly on heating, and returns to its former value on cooling, whereas molecular colloids show a relatively low temperature variation of viscosity. Moreover, the solutions do not obey the Hagen-Poiseuille law. The conclusion is drawn by de Chesne that the urea-formaldehyde resins consist of micellar aggregates of linear thread-like molecules of varying degrees of polymerization, which form highly solvated hydrophilic colloids possessing the property of irreversible gelation.

Another hypothesis concerning the mechanism of formation of urea-formaldehyde resins has been advanced by Redfarn<sup>71</sup> who attributes the resin formation to the polymerization of dimethyleneurea. In accordance with de Chesne's argument, dimethylolurea is first formed by the action of formaldehyde on urea. However, since the condensation is carried out in acid solution it is conceivable that two molecules of water may be eliminated to yield dimethyleneurea.

The reason why earlier investigations do not indicate the formation of such a structure may be that careful buffering of the reaction solutions was not practiced. The presence of dimethyleneurea should be realized at the stage where the first violent reaction has subsided. Further heating, then, results in polymerization, just as one would expect; the polymer being represented by Redfarn as a saturated chain.

In actual practice the heating is stopped when a thick, viscous syrup is obtained. After addition of fillers, the product is dried at gentle heat whereupon the syrup sets to a resin. This step is considered as the initial process of mutual saturation of the free end valences by ring formation. The saturation, then, is completed during the molding process.

According to Badarelli,<sup>72</sup> the urea-formaldehyde condensation products, especially those derived from thiourea, possess the properties of proteins, and should strictly be classed as artificial albumenoids rather than as synthetic resins.

## Chapter 27

### Urea Resins

#### I. Glass-Like Products. Castings

As has been already indicated in Chapter 26, urea and aqueous formaldehyde, that is, ordinary formalin, can be made to condense to a syrupy solution giving under some conditions a clear glass-like mass on evaporation. Since 1919, this reaction has been studied by chemists the world over in an endeavor to make a substitute for glass. Among the difficulties arising in the course of this work was the lack of permanency of the simulated glass prepared in this manner. For one thing, it was difficult to produce the so-called glass in a form which would be completely resistant to water. The urea-formaldehyde condensate, even when well dried, has a tendency to absorb moisture from the air in a humid atmosphere and to give it out again in dry air. During this "breathing," some action on the surface of the product may occur resulting in a variable dimming of the luster of the material. Furthermore, beautiful specimens of clear glass-like urea resins on standing for some time will almost inevitably form cracks and fissures because of changes in chemical structure (possibly with the elimination of water and formaldehyde) which create stresses and strains (see Fig. 90).

Of course, in articles designed for immediate and short-lived use, lack of permanency is not a handicap, but the flaws that may appear are detrimental in articles made to be kept and used over long periods of time. It has been found, however, that the presence of a filling material of the nature of cellulose fiber minimizes the stresses inherent in urea resins (see Chapter 28), and hence a molding industry of great importance has been established producing urea articles containing usually from 30-40 per cent of cellulose filler. Naturally, the addition of the filler destroys the product's transparent, glass-like appearance, but, on the other hand, thin molded articles containing the added cellulosic material are quite translucent. This translucent effect gives a depth or richness of appearance which would be difficult to equal with phenol-formaldehyde molded products.

#### THE UREA-FORMALDEHYDE CONDENSATION

John<sup>1</sup> prepared a glue by reacting urea or some of its derivatives (e.g., acetyl-urea) and an excess of formaldehyde at a relatively high temperature without adding a condensing agent. Thus, 5 parts of 40 per cent formalin are heated with 1 part of urea until nearly half of the liquid has been removed by distillation. The glue obtained is highly adhesive and adheres in the cold state to glass and metals. It may be admixed with pigments and is suggested for use in filling root canals (in dentistry) and as an impregnant for fabrics. The reaction product can be hard-

<sup>1</sup> H. John, U. S. P. 1,355,834, Oct. 19; 1920; *Chem. Abs.*, 1921, 15, 418. British P. 151,016, 1920; *Chem. Abs.*, 1921, 15, 1606. For a review of the development and characteristics of urea-formaldehyde resins, see J. Taylor, *Australian Plastics and Allied Trades Rev.*, 1933, 2 (2), 8; *Chem. Abs.*, 1934, 28, 661. For a brief review of the early literature, see W. Herzog, *Tech.-Ind. Schweiz. Chem. Ztg.*, 1924, 240, and A. E. Dixon, *J.C.S.*, 1918, 113, 238. See also J. Frère, *Kunststoffe*, 1925, 15, 92.

ened by heating to 80°C. By varying the method of procedure, John also obtained glass-like products.<sup>2</sup> In a gelatinized form, the material may be used as a substitute for rubber.

Goldschmidt and Neuss<sup>3</sup> added controlled amounts of acids or acid salts (not more than 0.5 per cent of the quantity of urea) during the condensation of the reactants. The coagulating effect of acids on the condensate had already been noted by Girsewald and Siegens.<sup>4</sup>

The proportion of formaldehyde necessary to produce clear resins is materially reduced by additions of acid condensing agents. Thus, by heating 100 g. of 30 per cent formalin with 20 g. of urea and 0.013 g. of hydrochloric acid at 100°C., a transparent product which hardens on prolonged heating is obtained. In case a glass-like transparency is not essential, the proportion of formaldehyde may be further lowered. If only 90 g. of formaldehyde solution are used, a milk-white resin is produced. Further reductions in the amount of formaldehyde and the use of larger quantities of acids result in the formation of porous masses resembling meerschäum.<sup>5</sup> As an example, 20 g. of urea are dissolved in 60 g. of 30 per cent formalin, with an addition of 20 g. of water, and heated until foaming occurs. If 5 g. of concentrated nitric, sulphuric or hydrochloric acid are then added, a strongly exothermic reaction takes place giving a porous mass upon cooling. Increase in the proportion of formaldehyde leads to the formation of a harder resin; a decrease, on the other hand, gives rise to a softer product. Ivory-like castings are formed by molding urea-aldehyde compositions in the presence of sulphuric acid.<sup>6</sup>

By adding formalin to fused urea, Neuss<sup>7</sup> obtained a chalky, porous, opaque substance. The urea (100 g.) is heated until molten, and 200 g. of a 40 per cent formaldehyde solution are added. A condensing agent, 4 g. of concentrated sulphuric acid, is introduced with the melted urea at the same time. The chalky reaction product, when washed, dried and hot-pressed, yields a horny, compact material. On heating 1 mol of urea with 3 or more mols of formaldehyde in the presence of a small amount of hydrochloric acid, Rothera, Blythen and Gillespie<sup>8</sup> obtained a gelatinous liquid which solidified when cooled.

Mittasch and Ramstetter<sup>9</sup> found that glass-clear products could be prepared by heating urea with at least 2.4 mols of formaldehyde in the presence of dilute mineral acids (e.g., nitric or phosphoric acids) or of acid salts. Alternatively, organic acids (oxalic, tartaric or acetic acid) may be used as condensing agents.<sup>10</sup> In the production of transparent resins, it has been found advantageous, in order to obtain stable bodies, to effect condensation under conditions of rigidly controlled acidity. By the use of buffer mixtures<sup>11</sup> (e.g., potassium hydrogen oxalate, mono- or disodium phosphate or citric acid and sodium citrate) the acidity is held between the pH limits 4 to 7. If water be then removed by evaporation at a temperature below 50°C., the solution may be considerably concentrated without premature gelation. The product may be hardened at 60-80°C. As an example of the use of this method, a warm concentrated solution of 6 parts of urea, containing 0.11 part of monosodium phosphate and 0.04 part of disodium phosphate is slowly

<sup>11</sup> British P. 258,289, 1926, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs. B*, 1928, 376.

poured into 25 parts of boiling 30 per cent formaldehyde. The product is evaporated *in vacuo*, at a temperature below 50°C., to a syrupy consistency, containing 10-15 per cent of water, and is stable for a considerable time. It may be cast in molds and hardened for 1 or 2 days at 65°C. without loss of clarity.

After effecting condensation at a  $p_H$  of 4-6 the  $p_H$  may be raised to 6-7 before concentration.<sup>12</sup> Clear products may be thus formed using a smaller proportion of formaldehyde than is otherwise possible. If a smaller molar ratio (1.5-1.7 mols of formaldehyde to 1 of urea) is used, evaporation may be partly or entirely dispensed with,<sup>13</sup> since the resin separates on cooling. The addition of salts (sodium sulphate) during the latter process is also suggested.

Knilling<sup>14</sup> fused urea and solid polymers of formaldehyde with the addition of small quantities of mild alkaline condensing agents (organic compounds giving an alkaline reaction) or sodium acetate and borax. Clear, colorless melts result which furnish white or glass-like masses according to the conditions of the subsequent hardening treatment. An intimate mixture of 200 parts of urea, 52 parts of thio-

FIG. 90.—Formation of Cracks in Clear Urea-Formaldehyde Resins.

urea (the addition of thiourea increases the transparency of the product), 240 parts of trioxymethylene, 6 parts of sodium acetate and 20 parts of formamide<sup>15</sup> is heated in an oil bath at 140°C. for about 20 minutes. The melt becomes viscous and is transformed on cooling into a hard, white mass which may be reduced to a fine powder. The powdered material is suggested for use as a waterproof adhesive in veneering wood.

Pollak<sup>16</sup> also described the use of alkaline condensation catalysts, using weak bases (pyridine, ammonia and hexamethylenetetramine). In the presence of these substances as catalysts, urea, heated with not more than 3 mols of formaldehyde, gives, after partial evaporation, a syrup which sets at 75°C. to a hard, transparent mass (sp. gr. 1.3) which is insoluble in both alkalies and acids. The cast resin undergoes carbonization at 300°C. without melting, and may be machined and turned. If condensation is first effected in the presence of a large excess of formaldehyde, that excess must be removed before the hardening step. The syrupy, partially condensed product may be used for impregnating porous material, and may

be mixed with mineral or cellulosic fillers. By incorporating dyes, substitutes for amber, coral, tortoise shell and mother of pearl are reported to be produced.

Oxides and carbonates have been suggested as condensing agents by several investigators.<sup>17</sup> Thus Barthélemy<sup>18</sup> used the carbonates of magnesium and the alkaline earths as condensing agents to bring about the union of urea and formaldehyde beyond the stage of methylolurea formation. On boiling 60 parts of urea with 200 parts of 30 per cent formaldehyde, with the addition of 6 per cent by weight of freshly precipitated calcium carbonate, a syrup is obtained which may be concentrated *in vacuo* to a hygroscopic, amorphous extract or a water-soluble gum, which behaves as a reversible colloid in contact with aqueous solutions of  $p_H$  8.6-10. By the addition of acid, whereby the  $p_H$  is changed to any value below 4, gelation of the gum takes place, yielding a horny mass which becomes transparent, and may be worked or polished on drying. Other heavy metal carbonates<sup>19</sup> (e.g., zinc or lead carbonate) and also the corresponding oxides (such as titanium oxide) catalyze the initial condensation. The use of these condensing agents has the advantage that the catalyst is rapidly removed completely by filtration, and the resulting products are desiccated with greater readiness. In addition, colored metallic carbonates (e.g., copper carbonate) serve as pigments for the resin.

Hydrogen peroxide was employed by Geisel<sup>20</sup> in the condensation of urea and formaldehyde at raised temperatures. The hydrogen peroxide (1 part of a 30 per cent solution) is stirred, with 44 parts of urea dissolved in an equal amount of water, into 196 parts of commercial formalin at a temperature of 70°C. As soon as reaction begins, the mixture is heated for a half hour at 100°C., after which it is concentrated *in vacuo* to a viscous liquid. On cooling, a clear, transparent mass is obtained.

According to Ramstetter,<sup>21</sup> both the condensation process and the curing process are accelerated by exposure of the resin to ultraviolet radiation from a quartz mercury arc lamp, the products under these conditions being harder, tougher and more resistant to water. The clouding tendency during the curing stage is also reduced or suppressed thereby.<sup>22</sup>

Kadowaki and Hashimoto<sup>23</sup> state that the optimum temperature for condensation is 85°C. and that the best results are obtained by adding the urea solution to the solution of formaldehyde. By drying the product at 60°C. and then at 100°C., the formation of gas bubbles may be avoided, although the investigators state that the resin tends to crack upon standing. Furthermore, it cannot be cast on account of shrinkage, and the thickness of resin stock obtainable is limited. These defects are reported to be overcome by hot molding during which the powdered condensation product is heated at 120°C. under 60 atmospheres pressure. As condensing agents, Kadowaki and Hashimoto advocate either weak inorganic acids, inorganic or organic bases or the salts of alkali and alkaline earth metals with organic acids.

Howald<sup>24</sup> produced a resin derived from ammonium cyanate. The ammonium cyanate (1 mol) is refluxed with 2 mols of the aldehyde (formaldehyde or acetaldehyde), the solution being kept neutral or slightly alkaline. The water is next removed, and fillers and plasticizers are added while the solution is still viscous. The mixture is dried, powdered, a fixing agent (urea or thiourea) for formaldehyde is added and the product is molded.

## THE PREPARATION OF METHYLOLUREAS

The investigations of Einhorn and Hamburger,<sup>24</sup> on the formation of monomethylolurea and dimethylolurea by condensing urea and formaldehyde in the presence of barium hydroxide have been discussed in Chapter 26.

To obtain dimethylolurea, they added 10 g. of urea to a solution containing 0.4 g. of barium hydroxide in 26.7 g. of 37.4 per cent formalin (2 mols of formaldehyde) and maintained the mixture at 25-30°C. until all the formaldehyde had reacted. The end-point of the reaction can be determined by Tollen's reagent (equal volumes of a 10 per cent solution of ammoniacal silver nitrate and a 10 per cent aqueous sodium hydroxide solution) which does not give a precipitate in the absence of formaldehyde. Carbon dioxide is then introduced at once to counteract the alkalinity of the barium hydroxide. The resulting liquid is dried in a desiccator without removing barium carbonate and the residue is extracted with warm 80 per cent alcohol. By cooling the filtered solution, 8 g. of dimethylolurea crystallizes out, and an additional 2 g. may be obtained by further cooling the mother liquor.

Monomethylolurea can be obtained, according to Einhorn and Hamburger, by slowly dropping 6.5 cc. of 37.4 per cent formalin into an ice-cooled solution of 5 g. of urea and 0.1 g. of barium hydroxide in 5 cc. of water followed by the immediate addition of carbon dioxide. The solution is filtered and evaporated in a desiccator, yielding the product as a crystalline mass.

Dimethylolurea is soluble in cold water and in warm methyl or ethyl alcohol, but is insoluble in ether and most other organic solvents. On heating, it sinters at 121°C. and melts at 126°C. forming a clear liquid which changes at 137-138°C. into an amorphous white material that does not melt on further heating but decomposes at 260°C. When dimethylolurea is heated in a test tube, the odor of formaldehyde and basic decomposition products is noted. The compound (in aqueous solution) gives a white amorphous precipitate on standing for several hours with dilute mineral acids.

Monomethylolurea, however, gives a flocculent amorphous precipitate almost instantly with dilute mineral acids and acetic acid. Cold water and methyl alcohol also dissolve monomethylolurea. Dimethylolurea reduces Tollen's reagent after some time, but monomethylolurea gives no formaldehyde reaction with sodium nitroprusside or phenylhydrazine.

Methylolurea or methylolthiourea and methylol derivatives of other acid amides may be prepared by the interaction of formaldehyde and the amide in non-aqueous solvents,<sup>25</sup> e.g., methyl or ethyl alcohol. The condensation is accelerated by basic substances, and the product may be precipitated by the addition of ether or carbon tetrachloride. By rapidly melting the compounds formed in this manner, with the addition of urea or thiourea and of acids (e.g., acetic acid) and buffer salts, clear or opaque resinous masses are obtained. In the preparation of dimethylolurea, the use of solvents in which the substance is not very soluble is advantageous, and formaldehyde polymers may be substituted for non-aqueous formaldehyde.<sup>26</sup> The methylol compounds of other acid amides (e.g., methylolacetamide) are similarly obtained.<sup>27</sup>

Dimethylolurea is also made<sup>28</sup> in aqueous, neutral or mildly alkaline solution

(e.g., 0.02-0.005 *N* caustic soda)<sup>29</sup> by concentration of the solution at a low temperature immediately after the reacting urea and formaldehyde are brought together.

The formation of dimethylolurea may be brought about at room temperature by the catalytic action of active carbon (e.g., a suspension of animal charcoal); pure and stable dimethylolurea is reported to result on evaporation after filtration from the carbon.<sup>30</sup> By heating the mixture under reflux, condensation proceeds further, yielding syrups of progressively increasing viscosity and decreasing solubility. These may be concentrated *in vacuo* to a material which solidifies to a clear, hard resin on prolonged heating at 60-100°C. This further condensation is retarded by the addition of alcohols, ketones, ethers or esters to the mixtures and reaction may be checked at any stage by such addition. The retarding agents are useful in preventing prematurely complete polymerization when condensation is effected in the presence of acids. The effect of retarding agents may be illustrated by an example cited by Gams and Widmer, in which 240 parts of urea are dissolved in 660 parts of 36 per cent formaldehyde, and 200 parts of ethyl alcohol added. The mixture is shaken with animal charcoal, filtered and boiled under a reflux condenser after adding 0.24 part of concentrated phosphoric acid in 20 parts of water. After several hours boiling, the liquid is still miscible with water and yields, on evaporation, a resinous syrup. In the absence of alcohol, the condensation of this mixture would proceed rapidly to completion.

#### POLYMERIZATION OF METHYLOLUREAS

Walter<sup>31</sup> found that glass-clear, transparent resins are obtained from monomethylolurea (m. p. 111°C.) and dimethylolurea (m. p. 126°C.) by rapidly melting the substances and maintaining them in the molten state, but below 140°C., until the mass, though viscous, may still be cast. Water and formaldehyde are thereby eliminated. The addition of fluxing agents, by lowering the melting point of the methylolurea, permits slower heating and eliminates much trouble due to frothing. Neutral and alkaline salts (e.g., calcium chloride or sodium acetate) or neutral mixtures of salt and acid (e.g., sodium acetate and glacial acetic acid) are satisfactory for this purpose, as also are urea, methylolamides and phenols. The addition of paraformaldehyde promotes the elasticity and flexibility of the product. With monomethylolurea, up to equimolecular proportions may be added, the use of acid fluxing and stabilizing agents being then desirable.

As an example of this process, 200 parts of paraformaldehyde are dissolved in a solution of 5 parts of caustic soda in 1100 parts of 94 per cent alcohol, and 200 parts of urea are added to the cold solution. After a few hours, the deposit of dimethylolurea may be separated. The dimethylolurea, when rapidly fused, undergoes violent foaming. If about 0.3 per cent by weight of chloroacetic acid be added to the clear melt, the mass rapidly thickens and may be cast in molds. Similarly, monomethylolurea containing about 2 per cent of sodium acetate may be fused after adding 1 per cent of caustic soda dissolved in a little water. The melt clears and finally gelatinizes, giving a glass-clear product which may be pulverized and molded under pressure at elevated temperatures.

According to Walter,<sup>32</sup> the polymerization of dimethylolurea or its mixtures with monomethylolurea, may be brought about by alkalies, giving as products resinous materials for molding compositions or lacquer ingredients. The polymerization is performed in the absence of substantial amounts of solvents, e.g., by mixing

dimethylolurea and monomethylolurea with 1-7 per cent by weight of caustic soda, either solid or in concentrated solution, and heating to 110-130°C. The products are hardened by heat and pressure.

In non-aqueous solvents such as ethyl alcohol, owing to the insolubility of the products, coupled with the decreased ionization of the alkalies, the action of strong alkaline condensing agents leads to the formation of mono- or dimethylolurea, without subsequent polymerization.<sup>33</sup> Anhydrous formaldehyde may be used in the form of trioxymethylene or paraformaldehyde. Thus, 130 parts of trioxymethylene are dissolved in 316 parts of methanol in the presence of 3 parts of 50 per cent caustic potash solution. To this are added 12 parts of caustic potash solution and 152 parts of thiourea. After a short time, resinous dimethylolthiourea precipitates and can be separated, washed with acetone and pulverized. Methylolurea or methylolthiourea so obtained may be fused rapidly and treated with a small quantity (not more than 1 per cent) of caustic alkali, whereupon the mass thickens and gelatinizes, finally setting to an opalescent product.

The separation of methylolurea in the solid form is not proposed if unmodified urea-formaldehyde resins are required. It is possible, alternatively, to effect preliminary condensation as far as or beyond the stage of methylolurea formation, then to polymerize the first condensation products by the addition of acid. A process of this nature has been described by Ripper.<sup>34</sup> The first stage of condensation must occur in neutral solution, e.g., by adjusting the  $pH$  to a value not lower than 7. Should the acidity rise above this value, white precipitates are produced which lead inevitably to the ultimate formation of a clouded or opaque resin. At a  $pH$  of 7, however, a water-clear solution is obtained, even with as little as 2 mols of formaldehyde per mol of urea. On cooling, cloudy solutions are formed which clear on heating, and on prolonged boiling yield viscous masses which harden to clear resins. In working by this process, either so-called acid-free formaldehyde may be used (e.g., that obtained by subliming the solid polymers in the absence of air) or ordinary formaldehyde may have its formic acid neutralized by addition of a base. The polymerization of the condensed substance may be brought about either by lengthy heating, or more expeditiously, by addition of sufficient acid to raise the  $pH$  to about 3. For this purpose, acid salts, acid esters or ammonium salts may be added. The latter function by reacting with formaldehyde to form hexamethylenetetramine, liberating the acid. Alternatively, formic acid may be formed *in situ* by aerating the mass. The acidity during polymerization should not rise above a  $pH$  of about 2.6 (corresponding to an amount of sulphuric acid less than 0.017 per cent of the urea employed), since gelation then occurs instantly, forming a hard, white, brittle material (containing all the water) which on standing loses water by evaporation, and becomes clear but readily crumbles to a powder.

By this process, 30 parts of urea are condensed by refluxing for a short time with 100 parts of neutral 30 per cent formaldehyde. Five parts of boric acid, dissolved in a little water, are added, and the mixture boiled for a further period. After 2.5 hours, the reaction mixture is converted into a moderately viscous solution which does not become cloudy on cooling, and which marks the polymerization of the initially formed methylolurea material into a colloidal hydrophilic sol. This may be hardened by evaporating most of the water, casting in molds and heating at 60-100°C. to give a transparent final product. More prolonged boiling of the mixture (6-7 hours) carries polymerization further, the clear, hot solution then depositing on cooling a white, slimy jelly from which the supernatant liquid may be decanted. The jelly, which is opaque due to adsorbed water, may be dried *in vacuo*, thereby being rendered transparent. It may then be cast in molds and cured. Boric acid may be

<sup>33</sup> G. Walter, U. S. P. 1,863,426, June 14, 1932, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1932, 26, 4142.

<sup>34</sup> K. Ripper, U. S. P. 1,687,312, Oct. 9, 1928, to F. Pollak; *Chem. Abs.*, 1928, 22, 4739. British P. 213,567, 1923; *Chem. Abs.*, 1924, 18, 2412. W. S. Rothera, S. Blythen and H. R. Gillespie, German P. 589,726, 1923; *Chem. Abs.*, 1932, 26, 2286.

replaced as a polymerizing agent by other acids, e.g., by adding 0.13 part of acetic acid, 1 part of ammonium acetate, 0.1 part of benzoic acid or a trace (of the order of 0.0005 part) of sulphuric acid.

Gams and Widmer<sup>38</sup> have described the preparation of porous materials of improved mechanical strength, free from electrolytes, by a process of initial condensation in neutral solution somewhat beyond the stage of dimethylolurea, followed by polymerization on the addition of a sufficient quantity of acid. A solid jelly is obtained which rapidly becomes white and hard and from which the catalyst may be eliminated by osmosis or, more rapidly, by electro-osmosis. If an acid catalyst is employed, it is removed by neutralizing and then washing the resulting

FIG. 91.—Combination Jar Mill.

salt. The specific gravity of the product may be as low as 0.4, if much solvent has been used. The application of high pressures increases the strength and density of the materials. The hardness of the product is governed by the nature and the proportion of the catalyst used, and may be further modified by the addition of softening agents, e.g., triphenyl phosphate, diethyl phthalate, linseed oil or latex. Fillers (e.g., cellulose and asbestos) and materials capable of taking part in the resin formation (phenol) may also be added. The products are characterized by considerable mechanical strength, toughness and good insulating properties. They may be machined and worked.

A process for the coagulation of the primary condensation product, described by Ripper,<sup>39</sup> depends on the flocculation of the substances from very dilute solution by further addition of solvent or by the use of flocculants (acids, bases or albumin precipitants such as phosphotungstic acid). No gelatinization occurs, but the mate-

rial is obtained as a white, amorphous powder which may be molded by heat and pressure. The powder is insoluble in water, but soluble in acids, hot formalin and in high-boiling hydroxylic solvents (glycerol). After molding, transparent or translucent resins are obtained which, according to Ripper, may be used as substitutes for crystal, glass or amber.

Porous masses of uniform consistency are formed<sup>77</sup> on gelatinizing the initial condensation product and partially hardening the mass without first concentrating the solution to any considerable extent. A large proportion of a dispersion medium (alcohol) may be added. Gelation may be effected by addition of acids or of ammonium salts. The effect of gelatinizing at high dilutions is to cause retention of the dispersion medium in the pores of the colloid. Since the dispersion medium is evaporated at a low temperature, the porous structure is retained leaving a translucent or meerschäum-like material, according to the pore size.

The gelatinization of the initial condensation product, i.e., the conversion of the hydrophilic to a hydrophobic sol, may also be effected<sup>78</sup> by introducing additional organic compounds capable of resin formation with the formaldehyde (e.g., urea or thiourea). Phenol may also be employed in this connection giving a soft, kneadable resin from which glass-clear masses may be made. The mixture is further heated in the presence of acid and on cooling, after neutralization, the resin precipitates as a viscous mass. The resistance towards water and the insulating properties of the cured resins are greatly augmented by this process.

Thus, 1500 parts of urea are boiled with 4000 parts of neutral 37.6 per cent formaldehyde solution, then 2 parts of formic acid and 300 parts of thiourea or 230 parts of urea (alternatively, 200 parts of phenol) are added. After 2 hours of boiling, the formic acid is neutralized by 2 parts of alkali carbonate, and the mass is cooled. The resin which separates may be repeatedly washed with water and then hardened in molds (being further dried by evaporation below 50°C.) or may be dissolved in 30 per cent of its weight of acetone to give a lacquer.

According to Gams and Widmer,<sup>79</sup> the condensation process may be considerably accelerated by carrying it out at a temperature above 100°C. under pressure, such conditions enabling complete control of the progress of the reaction and the required consistency of the product to be attained. Thus, 600 parts of urea dissolved in 1,645 parts of neutralized 36.5 per cent formaldehyde gave a completely soluble product when heated at 115°C. for 1-2 hours in an autoclave, and after 3-4 hours of heating at 120°C. yielded a clear, gelatinous gum. The same degree of condensation would be reached only after 17 hours heating at atmospheric pressure.

In general, concentration of the reacting mixture is necessary at some stage in order to remove the large excess of water in which resinification takes place. The reaction may, however, be carried out in more concentrated media, solutions containing up to 75 per cent of solid matter<sup>80</sup> being made by dissolving urea in the reagent obtained by the dissolution of the solid formaldehyde polymers in ammonia, alkaline formates and acetates or acids. The formaldehyde content of the solution may exceed 40 per cent. On boiling these concentrated reaction mixtures in an open vessel, viscous condensation products are obtained, hardening at 100°C. to clear, glassy masses.

The polymerization of the initial condensate, which is rapidly catalyzed by very small additions of acid, may be smoothly and slowly brought about by means of acetic anhydride.<sup>41</sup> Spontaneous gelation of the syrupy condensation products on standing may be suppressed, according to Ripper,<sup>42</sup> by the addition of alkali salts of weak acids (e.g., sodium borate or acetate). Solutions so treated harden only slowly on heating, enabling the latter process to be more readily controlled. The effect of the stabilizers may be neutralized by addition of sodium salts of highly ionized acids, which exert a strong accelerating influence. Stabilization of the urea-formaldehyde resins in the fusible jelly-like state is brought about also<sup>43</sup> by the addition of aqueous dispersions of mucilaginous substances (starch, gum tragacanth or karaya gum).

The gelatinization of the water-soluble condensation product which forms an intermediate stage in the resin condensation is accelerated by the addition of electrolytes.<sup>44</sup> This gelatinizing action shown by non-alkaline electrolytes divides salts into two groups. The first group contains electrolytes that rapidly convert the initial soluble product into hardened, insoluble resins. Included in this division are ammonium thiocyanate, ammonium sulphate and, in general, the ammonium salts of strong acids. The second division comprises salts that exert no hardening action, but do accelerate the gelatinization process. The sulphates, chlorides, nitrates and other mineral acid salts of the metals fall into this category, the anion being the active ion. The action is illustrated by the addition of 1 part of potassium sulphate, chloride or thiocyanate to 100 parts of the water-soluble condensation product from 60 parts of urea and 150 parts of 40 per cent formaldehyde. Gelatinization occurs, and water separates from the mass on standing in the cold. If thick articles are hardened in the cold by accelerating salts, the liberation of water in the interior of the mass is apt to cause cracking. This is said to be overcome by building up the mass with a plurality of layers, each being hardened before deposition of the next.

Before proceeding to hardening treatment, any acidity may be reduced by addition of bases or alkaline salts prior to gelatinization.<sup>45</sup> Cloudiness in the hardened material is controlled or prevented by the addition of salts.<sup>46</sup> Thus, after condensation with hexamethylenetetramine as catalyst, the acidity is determined and excess urea added to neutralize the acid as well as to bind free formaldehyde. Resin made in this manner, on molding, yields a cloudy mass, but addition of sodium chloride, sodium silicate, potassium iodide or other salt prior to hardening leads to the formation of transparent masses.

#### ACID HARDENING OF UREA-FORMALDEHYDE RESINS

The hardening step is accelerated by treating the uncured condensation products with weakly acid solutions of  $p_H$  4-7 (disodium phosphate). Hardening of

<sup>46</sup> The clearing action of the salts follows the order of the Hofmeister series of ions with slight variation. This series is based on the order of the ability of salts to coagulate albumin sola. For a constant anion the order of efficacy is:  $Fe^{++}$ ,  $Al^{+++}$ ,  $K^+$ ,  $NH_4^+$ ,  $Cu^{++}$ ,  $Mg^{++}$ ,  $Zn^{++}$ ,  $Ca^{++}$  and  $Na^+$ . With constant cation the anions were found to fall in the order: sulphate, citrate, oxalate, acetate, chlorate, carbonate, nitrate, bromide, cyanide, thiocyanate, iodide and salicylate.

the cast, uncured, gelatinous resin may be performed according to Luther, Griessbach and others<sup>47</sup> by exposing the surface to gaseous sulphur dioxide, or by immersion in an acetone solution of sulphur dioxide. The use of aqueous solutions, which frequently lead to surface opacity, is thus avoided. Products cured with sulphur dioxide are comparatively stable and, in contact with liquids, swell less than urea-formaldehyde resins hardened directly. The treatment with sulphur dioxide may be performed at an elevated temperature, effecting a rapid hardening. Various applications of urea-formaldehyde resins, as in the preparation of non-inflammable artificial fibers, are thus suggested.

In place of sulphur dioxide, other volatile acids may be employed as hardening agents,<sup>48</sup> e.g., formic acid, hydrofluoric acid, hydrochloric acid, solutions of the mineral acids (phosphoric and sulphuric acid) and also hydrogen sulphide.<sup>49</sup> Prepared in this manner, the viscous condensation product may be applied as an insulating lacquer to a metal surface. On exposure to formic acid vapor, the film loses its initially adhesive properties, forming a hard coating. Similarly, in the manufacture of molded lenses from transparent resin, the articles may be hardened at 60°C. until rigid enough to be removed from the mold without deformation. On exposure to hydrofluoric acid vapor for a day, or on dipping into 40 per cent hydrofluoric acid solution, the lens is stated to become hard enough for immediate polishing.

#### ELIMINATION OF FREE FORMALDEHYDE

The avoidance of any appreciable excess of free formaldehyde in the gelled polymerized mass is desirable, since its presence may lead to flaws and cracks during drying or during the molding process. Moreover, in the presence of much free formaldehyde the curing step seems to be retarded.<sup>50</sup> By adding substances which are capable of binding or decomposing free formaldehyde,<sup>51</sup> without forming gaseous bodies, the elimination of the excess of formaldehyde, and the transformation into clear, commercially practicable products is facilitated. Such substances are, notably, urea and thiourea, and also phenol. Alternatively, the formaldehyde may be destroyed by the addition of hydrogen peroxide.

The process may be carried out by making further additions of urea or thiourea to the gelatinous product of the initial condensation. Thus, 1 mol of urea is added for each 2 mols of free formaldehyde remaining after mixing 100 parts of urea with 600 parts of 40 per cent formalin and boiling until 60 per cent of the mixture has evaporated. The solution may then be concentrated at a temperature below 50°C. *in vacuo* until its viscosity has reached the highest value for which the operation of casting in molds is still practicable. The product, hardened at 60-100°C., is clear and does not become porous or clouded during molding due to liberation of formaldehyde. Moreover, the absence of gas evolution during curing at 100°C. aids the production of sharper moldings.

Pollak<sup>52</sup> described the preparation of transparent products free from uncombined aldehyde, in which urea is condensed with less than 2 mols of formaldehyde while

always maintaining some free formaldehyde in the reaction mixture, by the procedure of adding the urea gradually in progressively decreasing amounts. By a proper choice of the acid condensing agent, all the urea may be reacted before gelatinization occurs. A final acid polymerization may follow initial condensation in either neutral or alkaline solution.

Pollak<sup>53</sup> was of the opinion that restriction of the excess of formaldehyde present at any moment during the actual condensation did not permit of condensation being performed under optimum or even reproducible conditions. He thought the use of some excess was preferable, followed by removal of that excess, a step which may be performed either by reaction with further urea or thiourea or by the passage of a current of air or inert gas through the liquid at 80°C. Free, unreacted formaldehyde may thus be removed until its concentration has fallen to that value (usually 0.8-1.6%) which he considered necessary to avoid gelation of the resin.

Resins from urea and formaldehyde, said to be free from any deleterious products of side reactions,<sup>54</sup> may be obtained by mixing the condensation product of 1 mol of urea and less than 1.4 mols of formaldehyde with the product obtained by acid condensation of urea with more than 2 mols of formaldehyde, so that the ultimate ratio is about 1.8 mols of formaldehyde to 1 mol of urea. Thus, 60 parts of urea are dissolved in 347 parts of 30 per cent formaldehyde and boiled with 1 part of 10 per cent acetic acid. Then, 89 parts of urea are dissolved in 89 parts of 30 per cent formaldehyde, added to the first mixture during a period of 30 minutes and heated to complete the reaction.

Gams and Widmer,<sup>55</sup> in preparing resins free from excess formaldehyde, carry out the initial condensation in the presence of at least 2 mols of formaldehyde. Enough urea is then added that the mixture contains at least 1.05 mols of urea per mol of formaldehyde. A small proportion of an acidic compound is introduced at the same time. As an example, 320 parts of neutral 30 per cent formalin are refluxed with 120 parts of urea for 30 hours. After evaporation at a low temperature, 20 parts of urea and one-eighth part of sulphuric acid in 20 parts of water are added. No reaction occurs immediately. On evaporating the solvent water in a vacuum, there is formed a clear, viscous liquid, soluble in water, which hardens slowly on standing; the hardening takes place more rapidly on warming. The second portion of urea and the acid may alternatively be added at any stage during the concentration process. According to the final proportions of urea, the resins produced are transparent (with less than 1.1 mols of urea per 2 mols of formaldehyde) or translucent, becoming opaque with higher urea content. A stated advantage of this process is that the lowering of viscosity brought about by the second addition of urea enables dehydration to proceed much further before gelation occurs.

By incorporating a powdered reagent (urea or resorcinol) in a molding composition to fix liberated formaldehyde, glassy or porcellaneous products are obtained.<sup>56</sup> Sufficient urea may thus be added to bring the proportions down to 1.5 mols of formaldehyde per mol of urea. If desired, the secondary addition of urea may be made in such proportion that there still remains an excess of uncombined formaldehyde.<sup>57</sup> Free formaldehyde may be eliminated also by the addition of various sulphur compounds (hydrogen sulphide or ammonium sulphide).<sup>58</sup>

According to Rothera, Blythen and Gillespie,<sup>50</sup> the use of at least two molecular proportions of formaldehyde is desirable in the preparation of initially clear, glass-like, resinous materials. Smidth,<sup>51</sup> however, observed that transparency in the ultraviolet region, also resistance to weathering, was favored by a high proportion of urea. If two mols of formaldehyde be condensed with one mol of urea, in a solution of  $p_H$  above 4, the dimethylolurea first formed undergoes further condensation with elimination of formaldehyde, which according to Smidth follows the approximate equation:

If, now, the liberation of formaldehyde be followed analytically, further adequate quantities of urea<sup>51</sup> may be added to react with it, maintaining the proportion of 1 mol of urea added for each 2 mols of free formaldehyde. The addition of urea is best carried out in such a manner that there is always a slight excess of free formaldehyde.

In this manner, up to 1.3 mols of urea may be condensed with 2 mols of formaldehyde. Thus, 50 cc. of 39 per cent formaldehyde ( $p_H = 5.0$ ) were refluxed with 19 g. of urea, and after 5 minutes of boiling, 15 drops of 1 *N* formic acid were added. On boiling .25 minutes longer, 3 g. more urea were added, and the whole boiled for an additional 5 minutes. The solution was then concentrated under reduced pressure during which operation the addition of a further quantity of urea could be made.

A related process, involving the addition of urea to the syrupy concentrate resulting from the evaporation *in vacuo* of the initial acid-condensed product, has been developed by Goldschmidt and Mayrhofer.<sup>52</sup> Cloudy, vitreous substances are thereby obtained which become transparent on standing or on treatment with acetic acid or acetone. By progressively adding 0.73-0.75 mol of urea to 2 mols of formaldehyde in the presence of acid condensing agents, clear resins may be obtained which are suggested as substitutes for plate glass.<sup>53</sup>

#### THE DEHYDRATION OF UREA-FORMALDEHYDE RESINS

The critical and important process of dehydrating the gelled resin condensation products may be performed, according to Ramstetter,<sup>54</sup> by addition of organic solvents, e.g., glycol chlorohydrin, glycol monoacetate, formamide, formic acid and acetic acid, during the condensation. When these solvents are distilled off, the water is completely removed also, leaving a clear anhydrous resin. Other substances, capable of forming volatile mixtures with water vapor and of giving transparent solutions of the condensation product, may be used, e.g., glacial acetic acid, benzyl alcohol or glycerol.<sup>55</sup>

The addition of the organic substance may be made either to the reaction mixture, or to the concentrated product. In producing lacquers, repeated addition and distilla-

See also F. Pollak, British P. 238,904, 1924; *Chem. Abs.*, 1926, 20, 2652. W. S. Rothera, S. Blythen and H. R. Gillespie, German P. 567,271, 1925; *Chem. Abs.*, 1933, 27, 1464.

tion of low-boiling solvents may be employed to remove water. In place of a single added substance, two different organic compounds may be used. The first may be a volatile constituent, e.g., amyl acetate, to carry off the water from the resin, and the other may be a less volatile or non-volatile substance (benzyl alcohol, glycerol or sugar) which is largely retained and modifies the properties of the resin. For instance, the addition of borneol or camphor gives rise to very flexible, highly plastic products. As an example, 150 parts of an intermediate condensation product are dissolved in 50 parts of alcohol, and 5 to 10 parts of benzene are added. A ternary mixture of water, benzene and alcohol is removed by vacuum distillation, and a repetition of the operation displaces the water completely, leaving an alcoholic solution of the resin to which 2 parts of borneol, dissolved in 50 parts of alcohol, are added. The solution obtained is evaporated to a syrupy consistency, and yields a resinous body which is hardened at 100°C.

The principle of forming constant-boiling mixtures with organic substances has been applied also by Crump.<sup>66</sup> Urea, dissolved in part of the formaldehyde, is added to the hot bulk of the formaldehyde, and the mass is concentrated *in vacuo* while still in the soluble form. An organic liquid (e.g., butyl alcohol) is added and removed by boiling in an open pan. In this way water is very completely removed as a constant-boiling mixture.

Aqueous dispersions of urea-formaldehyde resins containing dyes, plasticizers or modifying agents may be dehydrated by spraying into a stream of gas heated to a temperature higher than the boiling point of water for the prevailing pressure.<sup>67</sup> Gases suggested for the purpose are air, carbon dioxide, helium or vapors of diphenyl oxide.

The addition of non-volatile substances miscible both with the urea-formaldehyde colloid and with water<sup>68</sup> (e.g., glycol), before concentration of the solution of the condensation product, also assists in the elimination of water. Cherry<sup>69</sup> reported that the addition of sucrose (20 per cent of the amount of urea used) enabled clear molded articles to be made without cracking.<sup>70</sup> Dearing<sup>71</sup> stated that gum acacia was analogous to sucrose in its action with urea condensates.

If the product is dehydrated by merely evaporating off the water, measurements of the specific electrical resistance (or conductivity) of the reaction mixture serve as indications of the rate of evaporation.<sup>72</sup> A mode of control is obtained by this means, and interruption of the process at a particular point is made possible.

Solvents may be removed from liquid urea-formaldehyde condensates by subjecting the dispersion to steam distillation, according to Pungs, Eisenmann and Kuchenbuch.<sup>73</sup> A hydrophobe gel is thereby obtained, from which much water may be removed by kneading or rolling. By rolling into thin strips, the substance may be dried more easily and thoroughly, becoming clear and glass-hard. The pulverized product may be first dried *in vacuo*, which gives a solvent-free material that can be molded. These investigators also extracted the solid condensation products with volatile non-hydroxylic solvents, e.g., ether, benzene or methyl formate, separating the resin into two fractions. One fraction is an insoluble, glass-like solid, the other, making up 15-20 per cent of the whole, is a colorless, viscous gum, which may be used as a softening agent for cellulose derivatives, or as

an adhesive. The solid fraction, like the original condensation product, is soluble in polyhydroxy compounds, higher ketones (e.g., cyclohexanone), furfural and ethers such as dioxane.

Feinmann<sup>74</sup> also fractionated urea-formaldehyde resins into portions with differing properties. The hot resin is treated with just sufficient water to cause separation into two layers after cooling to 15°C. The upper, aqueous layer is separated, and more water added to it to precipitate the condensation product. A separation is thus achieved of the insoluble and partially water-soluble fractions of the resin.

### ORGANIC GLASS

The various types of "organic glass" manufactured from urea-formaldehyde resins usually possess a transparency to ultraviolet light superior to that of ordinary

#### ULTRAVIOLET TRANSMISSION OF VARIOUS GLASSES

Fig. 92.

Comparison of the Ultraviolet Transmissibility of Various Glasses. (R. H. Crist)

Courtesy Industrial and Engineering Chemistry

window glass.<sup>75</sup> This fact, together with the resistance of the resins to discoloration on exposure to light, suggests their introduction as substitutes for ordinary glass. The observation that urea and formaldehyde would unite to form, on drying, a glass-like solid was formerly considered a discovery of the greatest importance. The announcement of this work was published in various journals discussing popular science and has led to much misapprehension. The statement has appeared that the clear material made in this way resembles glass in transparency but is much tougher and more serviceable in applications where the fragility of glass comes into question. These statements have not been borne out in actual practice.

In the first place the surface of the urea resin "glass" is soft relative to glass itself and is easily scratched. Likewise, because of its lack of adequate water-resistance, the surface becomes dulled on long exposure to humid conditions. The reaction between urea and formaldehyde, moreover, is not complete at the time

<sup>74</sup> I. Feinmann, British P. 397,909, 1932; Brit. Chem. Abs. B, 1933, 929. French P. 752,431, 1933; Chem. Abs., 1934, 28, 1293.

<sup>75</sup> For a short discussion of the light-transmitting characteristics of organic plastics, see Chem. Met. Eng., 1933, 40, 469.

the "glass" is prepared and the subsequent progress of the reaction tends to set up stresses and strains in the sheet or article made from the resin, resulting eventually in the spontaneous formation of cracks and fissures. Oftentimes these do not appear for a long period after the product has been made, but in due course they occur and the article made from the urea resin stock becomes disfigured and worthless.

One type of urea-formaldehyde resin<sup>76</sup> that has been developed in an attempt to find a substitute for glass is, when freshly prepared, transparent to both visible and ultraviolet light and has a specific gravity of 1.44. The refractive index of the product varies from 1.6-1.9, and the hardness is 2.95 on Moh's scale (the hardness of glass is 4.5-6.5). Its light-dispersive properties are similar to those of quartz crystal, which has suggested application to the production of optical parts. The material can be turned and does not melt on heating but chars at about 200°C.<sup>77</sup>

Crist<sup>78</sup> has made a study of the ultraviolet transmission of a proposed glass substitute consisting of a condensation product of formaldehyde and urea. The percentage transmission at different wave lengths is given in Table 32, and a comparison with other glasses is shown in Figure 92 taken from the work of Crist and that of Coblenz and Stair.<sup>79</sup> The sample used was clear, 3 mm. thick and had polished surfaces.

TABLE 32.—Transmission of Window-glass Substitute

Wave Length Å	Per Cent
2540	48
2700	56
3130	68
3650	74
4360	80

Kostka<sup>80</sup> observed that urea-formaldehyde resins show a readily distinguishable faint fluorescence when irradiated with ultraviolet light. However, phenol-formaldehyde resins, which absorb ultraviolet radiation, do not fluoresce. The ultraviolet opacity of the phenol resins affords a ready means of distinguishing them from urea-formaldehyde products. Katowaki and Kasai<sup>81</sup> found that urea-formaldehyde resin transmits rays having a wave length as short as 2300Å. A thio-urea-formaldehyde resin, cured at 55°C., is said to have the next best transparency. Both resins darkened on exposure to light of long wave length because of the presence of water in the resin. A methylurea-formaldehyde resin had a range of transparency similar to that of ordinary glass, whereas a product prepared from ethylurea completely absorbed all light in the ultraviolet region.

<sup>76</sup> This product, known as "Pollopos," was based on the work of F. Pollak of Vienna. It was sold in the United States as "Luxite" (*Plastics* 1929, 5, 350). See also C. Marx, *Plastics*, 1925, 1, 85. F. Pollak and K. Ripper, *Chem. Ztg.*, 1924, 48, 569, 582. H. R. Schulz, R. Schmidt and I. Schmidt, *Keram. Rundschau*, 1925, 33, 143; *Chem. Abs.*, 1926, 20, 1502. *Plastics*, 1927, 3, 400. *Ind. Eng. Chem., News Ed.*, 1927, 5, 15. *Oil, Paint and Drug Rep.*, 1926, 109(9), 21; *Chem. Abs.*, 1926, 20, 1891. A similar urea-formaldehyde product, "Prystal," has also been developed in an endeavor to produce a glass-substitute (H. Barthélemy, *Chim. et ind.*, 1926, 16, 367; *Brit. Chem. Abs. B*, 1926, 955. *Cf. Plastics*, 1927, 3, 324).

<sup>78</sup> R. H. Crist, *Ind. Eng. Chem.*, 1928, 20, 1367. The product studied was "Aldur" (See N. Klein, *Plastics*, 1928, 4, 588). Aldur was made by the Lucio Products Corp.

<sup>79</sup> W. W. Coblenz and R. Stair, *Trans. Illum. Eng. Soc.*, 1928, 23, 247, 1121; *Chem. Abs.*, 1929, 23, 944.

<sup>80</sup> G. Kostka, *Chem. Ztg.*, 1929, 53, 117; *Brit. Chem. Abs. B*, 1929, 293.

<sup>81</sup> H. Katowaki and Y. Kasai, *Repts. Imp. Ind. Research Inst., Osaka, Japan*, 1932, 13(3), 25; *Chem. Abs.*, 1933, 27, 1719.

Gams and Widmer<sup>82</sup> employed sheets of urea-formaldehyde resin (without any glass) in constructing a laminated material designed to replace glass in wind-shields and other products. For this purpose it is proposed to use the resin in two distinct stages of condensation, the less-condensed substance serving as an adhesive for sheets of the more highly polymerized material.

To obtain the more highly condensed resin, 5 kilos of urea are dissolved in 12.7 liters of 40 per cent formaldehyde, and the solution is filtered after the addition of 600 g. of animal charcoal. The filtrate is heated for 8 hours at 100°C. in an autoclave and evaporated at a low temperature. After adding 100 g. of phosphoric acid, the resin is cast in molds and hardened by increased temperature. The softer resin is prepared similarly, but together with the phosphoric acid is added 500 g. of benzyl alcohol as a softening agent. When the resins have been hardened into a workable glassy mass, thin sheets are cut, and a sheet of the soft resin is laid between two sheets of the hard resin. This combination of layers is then pressed for an hour at 100°C. and 50 atmospheres pressure. The resulting plate is further hardened by the usual methods until the polymerization of the resin is complete.

Capart<sup>83</sup> suggested that the strength and mechanical properties of glass-like urea resins could be improved by surfacing them with colloidal deposits of metals or metalloids. The metallic covering may be used, according to this investigator, as a conducting medium for the electrodeposition of other metal layers in the production of mirrors. Walter<sup>84</sup> hardened the surface of organic glasses by applying a harder, transparent varnish (e.g., a cellulose lacquer) as a coating.

When urea-formaldehyde condensation products are formed in water solution at a controlled hydrogen ion concentration, followed by evaporation of the solvent, drying and aging, strain is liable to develop and may cause cracking or disintegration of the molded product as has already been indicated. Smidth and Crist<sup>85</sup> heated a cast urea resin (prepared from 1.2 mols of urea and 2 mols of formaldehyde) in a bath of mineral oil at about 165°C. At this temperature the resin softens. The softening step is said to relieve strains causing possible deterioration, and at the same time the article can be shaped while in the plastic condition. The heating time is generally 1 minute.

Müller<sup>86</sup> formed transparent, glass-like materials by molding urea-formaldehyde condensation products in closed molds made of non-metallic substances (e.g., glass and plywood) and dried the molded articles in a moist medium until the specific gravity no longer varied. Before completion of the drying, the molded piece was compressed. Specifically, 80 kg. of paraformaldehyde, 50 kg. of water and 63 kg. of urea are heated with 4 liters of 2 *N* sodium hydroxide, until dissolved, and then refluxed for 1 hour. A condensation product (10 kg.) of glycerol and adipic acid is added, and the refluxing is continued. Then 6 kg. of 2 *N* sulphuric acid, in which 2 kg. of urea are dissolved, are introduced into the mixture, and the whole is boiled until clear. The resulting liquid is cooled in the prepared molds and removed after 6-8 hours as a homogeneous, transparent, molded article ready for the drying process. The drying is accomplished by treating the product with air of progressively rising temperature and diminishing humidity. During the air-drying, the article is rested on a support having a shape similar to that of the original mold.

Urea plastics were used by Ramstetter<sup>87</sup> for making lenses and optical parts. Reference also may be made here to a method of manufacturing large disks from urea-formaldehyde resins.<sup>88</sup> The principal features of the method include the use of large, closed vertical molds made of acid glass and the drying of the molded disks in an air stream of gradually rising temperature and a humidity 10-40 per cent below the saturation pressure of water vapor at the prevailing temperatures.

## Chapter 28

### Urea Resins

#### II. Hot-Molding Compositions. Fillers

The conditions for making a satisfactory molded product in which urea resin<sup>1</sup> forms the binding agent or plastic material are very complicated. For one thing it has been found useful in reacting urea and formaldehyde to maintain a definite pH control<sup>2</sup> because the degree of acidity or alkalinity of the composition materially influences the flow or plasticity of the molding composition. It is also necessary to have a composition available which on molding shrinks very slightly in the mold and gives sufficient opportunity to remove the finished article easily. At the same time, shrinkage must not be great enough to exceed the tolerance limits for the dimensions of the molded piece.

Another point which should be noted in connection with products of the kind under discussion is that a molded article from a urea resin tends to absorb moisture in humid weather and to give it out in a dry atmosphere. Thus there progresses a constant, very slight expansion due to moisture take-up and a corresponding shrinkage when such absorbed water is removed by drying. This change, however, is so slight that it does not result in fracture of the molded article.

Due to this attraction for moisture, molded articles from urea resins are not absolutely water-resistant, and the degree of resistance depends in a large measure on the method of making the molding composition as well as on the degree of cure. It is customary in testing the molded articles to boil a specimen in water for a given time, remove, dry and note the character of the surface. At the same time weighings are frequently made to determine the amount of water-absorption under the conditions of this test. Should the molded specimen, after drying, present a smooth, glossy surface, it is usually considered satisfactory but, on the other hand, if blisters have formed or disintegration has set in with deformation of the article, the product is not acceptable for most purposes.

One important advantage which the urea resin molding compositions possess over those of the phenol-formaldehyde type is the relative translucency of the molded goods. It is possible to add colors to a refined phenol-formaldehyde resin and obtain very good shades, especially with the darker pigments, but articles molded from compositions so pigmented are decidedly opaque, lacking the slight measure of transparency or translucency of surface which gives to the molded articles from urea resin a brilliancy and depth of color that is not easily obtained by any other thermosetting composition.

<sup>1</sup> For reviews concerning the use of urea-formaldehyde products in the molding field, see: Carleton Ellis, *Chem. Met. Eng.*, 1928, 35, 18; *Ind. Eng. Chem.*, 1934, 26, 38. J. Scheiber, *Farbe u. Lack.*, 1931, 170; *Chem. Abs.*, 1931, 25, 3501. F. Schmidt, *Kolloid-Z.*, 1923, 46, 324; *Brit. Chem. Abs. B*, 1929, 125. W. C. Hirsch, *Elec. Mfg.*, 1931, 7, 49. A. A. <sup>2</sup> See M. Dérivière, *Rev. gén. mat. plastiques*, 1933, 9, 466; *Chem. Abs.*, 1934, 28, 3191. See also Chapter 27.

Molding compositions containing urea resins can be processed to yield articles which are white, ivory or cream colored, and by the addition of pigments the pressed articles may be given a variety of the lighter tinted shades which are particularly desired.

Much study has been devoted to the problem of obtaining colors or pigments for the urea resin compositions which will give molded articles that are fast to light while still possessing light tones or pastel shades. In the manufacture of molding compositions difficulty arises in matching colors. A product may be made of a given shade and sold and then, when the consumer of the molding composition wishes to duplicate his order, the factory has to produce the same shade. This may be of a delicate cast and difficult to reproduce, hence the plants producing the molding compositions have on hand men who are experts in color matching.

The earlier products placed on the market were prepared by reaction between formaldehyde and mixtures of urea and thiourea. These substances react with formaldehyde in the same manner, that is, they yield methylol derivatives which condense to resins, but although equivalent in a generic sense the urea resins are displacing those from thiourea or from mixtures of urea and thiourea. The latter gives strength to the molded article but retards the rate of cure, with the result that the resins containing thiourea are not particularly in favor with a molder who seeks to obtain from his presses a large daily production. A further disadvantage arises in the action of thiourea on the steel molds used in molding establishments. Sulphur present in the thiourea blackens an ordinary steel mold and in the course of time the surface of the mold is impaired and consequently the molded articles do not possess the desired surface finish. To offset this, stainless steel or chromium-plated molds have been used, but the cost of molds, even when made from cheaper grades of steel, is so high that any additional cost of mold making is frowned upon by the molders who require such equipment. The plating on molds protected in this manner is worn off in the course of time, especially at projecting parts of the mold walls where the flow of the composition is particularly severe and renewal of the plating is then needed. In view of these disadvantages the use of thiourea with urea is comparatively limited, although in some cases where a particular degree of strength and high water-resistance is required a portion of the urea may be replaced by thiourea.

The specifications of the molder with respect to flow of the material, surface finish and particularly absence of blistering are extremely precise and the manufacturer of urea resin molding compositions has to conduct his manufacture in the most exact manner with every possible method of control in hand in order to meet these requirements (see Figure 93). If a molding composition during hot pressing generates gases too easily the molded article will show blisters either on the surface or in the interior, which of course cause distortion and defacement. It is sometimes customary, in molding plants where urea resin molding compositions are used, to relieve the mold of gases by raising the platen during the earlier stages of cure. If a very rapid molding composition is being used, it is generally sufficient simply to apply pressure, then immediately relieve the pressure and after the escape of gas, which occurs quickly, the press is closed until the cure is effected.

As urea resin molding compositions are desired particularly to provide molded articles which are white, ivory-colored or of various delicate shades of color, the problem arises of avoiding the introduction of dirt and dust into the molding composition and also of molding under conditions which preclude the inclusion

of foreign matter. In the resin factory it is possible to filter the air entering the plant and to conduct the manufacturing operations with due regard for cleanliness in an effort to prevent the entrance of foreign particles. The molders, however, are not so well situated, since their plants as a rule are operating on phenol-formaldehyde products, which are generally dark in color. Therefore there is much dust in such molding establishments which is liable to get into the light-colored molded urea resin pieces and cause stains and specks. The defacement which results thus may cause a considerable number of rejections. Further, it should be noted that molds which have been used for phenol-formaldehyde products generally are difficult to clean adequately for use in molding light-colored urea resin articles. For this reason it is recommended that the molder avoid make-

shifts and have a building or department for molding urea resins entirely separate from the phenol-formaldehyde work and to use every possible care to keep the urea-formaldehyde section free from dust. In the past a number of complaints which have arisen because of rejection of urea moldings have been blamed on the manufacturer by the molder, when in reality the molder himself may be responsible due to operation in an inappropriate, dusty environment.

#### ACID CONDENSING AGENTS

It was found by Ellis<sup>3</sup> that the wide range of temperature between the hardening points of the methylolureas and their decomposition temperatures renders them especially suited to the manufacture of firm, heat-resistant, molded articles. Thus, dry dimethylolurea gave a white material which could be molded at 150°C. under 1000 lb. pressure. The glossy molded product carbonized and burned, without melting, when held in the flame of a Bunsen burner. Resins of this type also may be incorporated in phenol-formaldehyde or phenol-furfural resins, making modified molding compositions. Aniline-furfural resins, phenol-sulphur resins or

<sup>3</sup> Carleton Ellis, U. S. P. 1,536,881, May 5, 1925; *Chem. Abs.*, 1925, 19, 1956.

natural gums (cracked Congo resin) are also capable of incorporation with methylolurea.

In the preparation of molding compositions, the acid used to bring about polymerization of the urea condensation product is, to some extent, retained by and catalyzes the hardening of the resin. Hence, those acids having no deleterious action on the mold are desirable. Thus,<sup>4</sup> dimethylolurea may be "polymerized" by

*Courtesy Hydraulic Press Mfg. Co.*

FIG. 94.—Battery of Small Hydraulic Presses.

phthalic anhydride or oxalic acid. By keeping the composition slightly acid, the material is less likely to be discolored on heating than if alkalis are present.

The nature of the acid condensing agent used may have some effect on the properties of the resins formed.<sup>5</sup> If 20 parts of urea be mixed with 54 parts of 40 per cent formaldehyde, in the presence of 0.4 part of caustic alkali, condensation may be checked at the stage of dimethylolurea by neutralization with acetic acid or phthalic acid as soon as a turbidity appears. The resulting solution, which is stable indefinitely, may be coagulated (e.g., in a mold) by the addition of a small quantity of strong acid. Modifying agents such as casein, gelatin, dyes or fillers are added. The castings are allowed to stand until hard enough to handle,

<sup>4</sup> Carleton Ellis, U. S. P. 1,536,882, May 5, 1925; *Chem. Abs.*, 1925, 19, 1956.

<sup>5</sup> Carleton Ellis, U. S. P. 1,846,853, Feb. 23, 1932; *Chem. Abs.*, 1932, 26, 2609

then dried superficially in the air. The material can be machined, and if water is expelled by heating, the product becomes transparent and hard. The mineral acids or acid salts used for coagulating may, however, be replaced by organic acids. For example, when urea, phthalic anhydride and aqueous formaldehyde are heated together they form a thin, transparent syrup which becomes heavy-bodied on cooling. This may be diluted with alcoholic or ketonic solvents (e.g., with an equal bulk of acetone) to form varnishes or impregnating media that yield transparent coatings when baked. The condensation product embodying phthalic anhydride is more resistant towards discoloration by heat than the unmodified urea-formaldehyde resins.

A resin of this type is made by boiling 15 parts of urea with 15 parts of phthalic anhydride and 60 parts of 40 per cent formaldehyde, then drying at 50°C. until the material can be cut into strips or sheets, which on air-drying give a clear, glassy material that is suggested as a substitute for glass for some purposes. By baking at 110-130°C., the material is rapidly made insoluble and can be used as a molding composition. Employed in this manner, with asbestos, wood flour or other filler, molded articles leave the mold freely, no mold-lubricant being necessary. In compositions of this type, phthalic acid is replaceable by other acids, e.g., benzoic acid, citric acid, gallic acid and trichloroacetic acid, giving rise to a considerable variation in the toughness, color and other properties of the products.

A study of these various acid condensing-reagents was made by Ellis\* who found that although mineral acids scarcely enter into combination with the urea-formaldehyde products, organic acids have a greater tendency to form resinous complexes. In the following succinct account of the experimental findings, 1 part of the designated acid is boiled with 1 part of urea and 4 parts of a 40 per cent formaldehyde solution:

(1) Benzoic acid gives a white, opaque, syrupy liquid containing much crystalline material, after boiling for 5 minutes. This substance hardens readily to a fairly white product when heated on a hot plate.

(2) With citric acid the mixture effervesces on heating, giving a clear syrup. On a hot plate, the material rapidly hardens with slight yellowing.

(3) The reaction is exothermic with acetic anhydride and a clear, white jelly is obtained. A snow-white, infusible, glossy mass results on the hot plate.

(4) Propionic acid gives a mild reaction leading to a white, non-syrupy solution. A transparent, hard, white mass is obtained by heating on a hot plate.

(5) On heating the ingredients with gallic acid, a clear, thick, syrupy solution forms, which becomes clouded and slightly yellowish on heating. Hot-plate treatment gives a hard, glossy, yellowish resin.

(6) Lactic acid gives a clear, syrupy solution which hardens to a yellowish resin on the hot plate.

(7) Boiling the ingredients with maleic acid yields a slightly yellow, thin syrup (free from sediment) which gives a spongy, brownish, rather weak mass on the hot plate.

(8) Treatment with salicylic acid results in the formation of a water-white syrup with some white, crystalline residue. If this is heated on the hot plate a tough, snow-white resin forms readily.

(9) When tartaric acid is heated with the mix, effervescence is observed and a clear, not particularly syrupy solution results. Heating on the hot plate gives a fairly tough, pure white resin.

(10) Acetyl salicylic acid forms a thick syrup, transformable into a transparent jelly. This reacts very quickly on the hot plate to produce a transparent resin.

(11) With oxalic acid, a clear, rather thin, light-colored syrup is obtained which on heating (hot plate) sets to a hard mass.

(12) A white syrup with much white solid matter resulted on reacting the materials with mucic acid. Hot-plate treatment converts the product to a white resin, tougher than that obtained with maleic acid.

(13) By using tannic acid, a yellow solution passing through a syrupy stage to a

\* Carleton Ellis, *loc. cit.*

thin, transparent, yellowish brown jelly is obtained. After a brief hot-plate curing, a dark brown resin remains.

(14) A vigorous, jelly-forming reaction occurs with trichloroacetic acid. Further curing gives a white resin possessing considerable elasticity

(15) Stearic acid gives a poor reaction with much separation. The product obtained on the hot plate is opaque and lacks strength.

According to Luther and Haag,<sup>7</sup> water-soluble, crystalline products are obtained by the condensation of at least 2 mols of urea with 1 mol of formaldehyde by means of acid condensing agents in organic solvents (e.g., ethyl acetate). In water, condensation proceeds further, forming substances differing from methylencurea in that they are soluble in hot water. Having a lower solubility than

urea and a high nitrogen content, these bodies have been suggested for use as fertilizers and fungicides.

In the preparation of resins containing less than 2 mols of formaldehyde per mol of urea, condensation products very low in retained water are obtained by adding to the reaction mixture buffer compounds which, at the same time, reduce swelling.<sup>8</sup> The substances used for this purpose are the polybasic organic acids (citric acid), their salts and the salts of aluminum and other polyvalent metals with organic acids.<sup>9</sup> These are employed as the sole buffering agents.

Salts and other compounds undergoing acid hydrolysis are also used.<sup>10</sup> Such

substances are magnesium chloride, formamide and formic ester. Thus, 1200 parts of urea in 800 parts of water are condensed with 4000 parts of 30 per cent formaldehyde in the presence of a sodium acetate-acetic acid buffer. After condensation, 7 parts of dilute sodium acetate solution are added, and the mixture concentrated *in vacuo*. Before completion of the evaporation step, a concentrated solution of 10 parts of magnesium chloride is added. The viscous product is completely hardened by keeping at 70°C. for 12 hours.

#### $p_H$ CONTROL

Ellis<sup>11</sup> observes that, between the  $p_H$  limits 4-8 customarily used for the initial stage of condensation, the time required for reaction varies with the hydrogen-ion concentration. At the same time, the  $p_H$  of the mixture changes slightly during reaction, e.g., from 6 to 5.1. The time required for drying the resin is also related to the period of heating during condensation. If the latter operation be advanced as far as possible in the liquid phase without gelation, the drying is expedited and may be carried out in air or in a vacuum drier, below 50°C. Avoidance of pre-curing during drying is essential if the molding properties of the resin are to remain unimpaired.

Cherry<sup>12</sup> recommended that the condensation of urea and formaldehyde be carried out at a  $p_H$  of 5. This value is attained in commercial formaldehyde solutions (containing usually 0.02-0.03 per cent of formic acid) in the presence of lead, manganese or other heavy metal acetates as buffering salts. In the presence of a reactive metal (zinc), the formic acid reacts to yield zinc formate, which exercises a buffering action. According to another procedure,<sup>13</sup> condensation may be carried out at a  $p_H$  of 3, and the  $p_H$  of the solution raised to 7 before it is concentrated. The final reaction of the concentrated product may then be effected by acidifying so that the  $p_H$  is between 3 and 5. Goldschmidt and Gerische<sup>14</sup> prepared condensation products by refluxing paraformaldehyde, urea and a small amount of 2 *N* sodium hydroxide. Sulphuric acid was then added and heating continued until a viscous mass was formed. After adding ethyl alcohol (or other lower alcohol), the mixture was cooled. The product remained fluid for several days and then gelatinized. A modification of this reaction entails the use of trioxymethylene, butyl alcohol, urea, 0.5 *N* sodium hydroxide and 0.5 *N* sulphuric acid.<sup>15</sup> The method employs super-atmospheric pressures by performing the reaction in an autoclave heated to 135°C.

The formaldehyde used in urea-aldehyde condensations can be treated with magnesium carbonate to control the  $p_H$  of the reaction mixture. Thus, Ellis<sup>16</sup> added 10 parts of light magnesium carbonate (this may be prepared from cold dilute solutions of magnesium sulphate and sodium carbonate) to a mixture containing 840 parts of urea, 300 parts of thiourea and 2250 parts of formalin. The initial  $p_H$  of 7 changed to 8.4 on heating over a period of 10-12 minutes up to 65°C., and at the temperature

<sup>16</sup> Carleton Ellis, U. S. P. 1,905,999, Apr. 25, 1933, to Ellis-Foster Co.; *Chem. Abs.*, 1933, 27, 3629.

of boiling the  $p_H$  was 7.8. According to Dearing,<sup>17</sup> a stable formaldehyde solution with a  $p_H$  of 7.1 can be obtained by adding 2.5 per cent (by weight) of basic magnesium carbonate to commercial formalin. This solution maintains its neutrality over long periods of time.

Two or possibly three factors influence the production of water-soluble urea-formaldehyde condensates; these are (1) the  $p_H$  of the condensing medium, (2) the ratio of urea to formaldehyde, and (3) in some cases on the rate of addition of the urea to the formaldehyde. By reacting 1 mol of urea with 2 mols of formaldehyde in a medium having a  $p_H$  of 5, Dearing<sup>18</sup> obtained a condensate which gave a water-insoluble precipitate upon dilution with a large amount of water after the elimination of free formaldehyde. The product, which may be molded with heat and pressure, is at first fibrous, but becomes amorphous after washing with fresh quantities of water.

Dearing<sup>19</sup> prepared a molding powder by employing an initial  $p_H$  of 5 and adding acid to complete the condensation. Thus, 800 parts of water and 60 parts of urea are added to 300 parts of formalin (adjusted to a  $p_H$  of 5). The solution is boiled for one minute, and 30 parts of urea are introduced. After an additional one minute interval 21 parts of urea are added; and the refluxing is continued for one hour, adding 2 parts of hydrochloric acid (sp.gr. 1.18) at the end of this period. The solution is boiled five hours longer with the subsequent addition of 5 parts of hydrochloric acid. While the reactants are refluxing for 14 hours more, a copious precipitate is formed which is separated, washed and dried.

Organic bases which do not react with formaldehyde (e.g., triethanolamine) may also be used to adjust the  $p_H$  of formaldehyde solutions.<sup>20</sup> Formalin so treated and brought to a  $p_H$  of 5-6<sup>21</sup> may be condensed by progressive addition of urea until a half molar proportion of urea has been added, and the reflux mixture concentrated to a thick syrup. If the  $p_H$  be then brought to 7-7.5, formaldehyde remaining free may be fixed by incorporation of a further quantity of urea or thiourea. If esters of polybasic acids with polyhydric alcohols, which serve as plasticizers, are added, the  $p_H$  of the concentrated product may be lowered to 3.5-5, the resin being then dried *in vacuo* at not too high a temperature (80-140°C., depending on the article to be made). The products, containing formaldehyde and urea approximately in the proportion 1.75:1, may be molded and cured by the application of heat and pressure. By condensing 1 mol of urea with a moderate proportion of formaldehyde (1.05-1.55 mols) at 30°C. in a solution with a  $p_H$  of 4-7, followed by evaporation at 60°C., products useful as molding compositions are obtained.<sup>22</sup> As above, the adjustment of  $p_H$  may be effected by the addition of organic bases, e.g., triethanolamine or guanidine. Substances (e.g., saccharin) which lose their acid character during the reaction have been suggested for the polymerization of the urea-formaldehyde condensates.<sup>23</sup>

Griffith<sup>24</sup> considered that the addition of guanidine confers a much greater

latitude as to the  $p_H$  at which condensation may be effected without detriment to the color and transparency of the product. As little as 0.5 per cent of guanidine exercises a marked effect, whereas if 30 per cent of the urea be replaced by guanidine carbonate, hard, colorless resins may be produced by condensation at a  $p_H$  of 4-6. If, however, guanidine be substituted for urea entirely, satisfactory resins may be produced by condensation in a solution of any acidity between the  $p_H$  limits 3-10. When mixtures of urea and guanidine carbonate are employed, the acidity may conveniently be adjusted by addition of acid, using methyl red ( $p_H$  of color change is 5-6) as indicator. The curing of resins containing guanidine is said to proceed more rapidly than with resins containing urea only.

Condensation products that are soluble in water and are reversible gels can be prepared, in the dry state or in solution, by condensing urea and formaldehyde without going beyond the hydrophile stage.<sup>25</sup> The reaction is performed without accelerators, and the dry resulting material dissolves as a clear hydrosol that can be employed in the preparation of varnishes, impregnants or molding powders.

The polymerization or further condensation of dimethylolurea may be carried out by heating a solution or suspension of the compound in the presence of a phosphate, acid potassium oxalate or tartaric acid buffer which maintains the  $p_H$  at 4-7.<sup>26</sup> Such a solution may be circulated through heated tubes where condensation occurs, passing finally into a vacuum spray-drying chamber where the resin is dried to powder form. Buffered suspensions in non-aqueous solvents (monohydric or polyhydric alcohols) may also be employed.

## ALKALINE CONDENSING AGENTS

The condensation of urea with formaldehyde in the presence of small quantities of basic substances (e.g., barium hydroxide) was found by Einhorn and Hamburger<sup>27</sup> to lead to the formation of dimethylolurea (see Chapter 27). Basic catalysts thus can be used as condensing agents for bringing about the first stage of condensation in the manufacture of urea-formaldehyde resins. Urea may be treated with formaldehyde in the presence of a base, the solution then being neutralized, acidified to bring about gelatinization and poured into molds to solidify.<sup>28</sup> In place of formalin solution, paraformaldehyde may be employed<sup>29</sup>

Courtesy Pittsburgh Lector dryer Corp.

Fig. 97.—Air Dryer for Urea Plastics Temperature and humidity are automatically controlled.

in the presence of just sufficient alkali to bring about condensation as far as the stage of dimethylolurea. The general procedure<sup>30</sup> is to dissolve urea in rather more than 2 mols of formaldehyde, with a small proportion of calcium or barium hydroxide. Dimethylolurea does not immediately separate, and on acidifying the solution with a mineral acid the liquid sets to a white mass with the evolution of heat, becoming quite hard in the course of a short time. The outer layers of a thick mass of the substance are usually translucent, becoming clear on drying *in vacuo* or at room temperature, while the interior is white and opaque. Shrinkage occurs during drying, causing cracking and disintegration of the material. If the mass be poured out and dried in thin layers, the milky solid formed may be pulverized, and may then be molded in a hot press (e.g., under 4000 lb. pressure

<sup>27</sup> A. Einhorn and A. Hamburger, *Ber.*, 1908, 41, 24; *J.C.S.*, 1908, 94 (1), 141.

at 160°C.) to give transparent materials. A molding pressure higher than that used with most plastics is desirable.

The molding powder thus obtained still contains the acid used for polymerization. This may be washed out, or it may be neutralized by incorporating a small quantity of alkaline material in a mineral filler. The coagulated mass is hard and elastic; it is unaffected by cold water, but disintegrates slowly in boiling water. After molding, the resistance towards water is found to be improved. The clarity of the cured material increases with the completeness of the dehydration of the molding composition.

The degree to which polymerization proceeds, and therefore the plasticity of the product, depends upon the temperature at which condensation occurs. Urea-formaldehyde solutions in contact with zinc carbonate or zinc oxide assume a  $p_H$  of about 6,<sup>31</sup> at which figure condensation proceeds at room temperature, yielding stable solutions of a low degree of polymerization, hardening on long standing to a fusible, crystalline mass which may be dried and hot-molded in the presence of an acid hardening agent. Alternatively, the melted crystalline material may be used to impregnate porous fillers (cellulose, asbestos). The fillers may be introduced into the solution in which condensation actually occurs. The materials so obtained, after hot-pressing, are said to possess higher mechanical strength than those condensed at high temperatures.

By another process,<sup>32</sup> ammonium salts or the salts of aromatic or aliphatic amines are added to the urea-formaldehyde mixture, rendering it acid towards methyl orange but still alkaline to tournesol. Metallic oxides, hydroxides or basic salts may then be introduced to promote condensation. According to Arnaud,<sup>33</sup> the presence of carbohydrates (levulose, glucose, sucrose, dextrin) is advantageous in the process. The incorporation of a proportion of glucose has also been employed by Manesse and Sechehaye<sup>34</sup> and by Israel<sup>35</sup> with zinc oxide as the catalyst. By this method, 2700 g. of 40 per cent formaldehyde are mixed with 1000 g. of urea, 400 g. of glucose and 15 g. of zinc oxide. The reaction, at first endothermic, becomes exothermic. The mixture is heated until 800 cc. of water have distilled, and then concentrated under reduced pressure until 1600 cc. of aqueous distillate have been recovered. At this stage, the material is placed in molds and heated for 36 hours at 80°C. Sugars (glucose and lactose) may also be used as condensing agents and dehydrating compounds in the presence of ammonia or of ammonium salts.<sup>36</sup>

Keller<sup>37</sup> utilized copper sulphate as a catalyst for the initial condensation process. The dry-stage reaction of urea and solid, anhydrous polymers of formaldehyde was carried out by Keller<sup>38</sup> with the aid of a combination of basic and acidic catalysts, and led to the formation of clear, transparent, viscous condensation products. A dry mixture of urea and paraformaldehyde with a small amount of the alkaline catalyst (sodium hydroxide, sodium bicarbonate or other basic salt) is moistened with saturated steam. Then an acid catalyst (e.g., acid sodium phosphate) is introduced and heat is applied to complete the reaction. Calcium chloride<sup>39</sup> and the other alkaline earth chlorides may be used as condens-

ing agents. Formaldehyde and urea are mixed with 15-60 per cent by weight of calcium chloride, boiled to complete the methylolurea condensation, and finally polymerized by boiling with acid.

#### USE OF FORMALDEHYDE POLYMERS

Urea or thiourea mixed with solid polymerized formaldehyde and fillers, in the absence of water or volatile liquids, yields a product that can be hot-pressed directly.<sup>40</sup> Binding agents, pigments and fire-resistant materials may also be added to the mix. The condensation can be carried out in a melt of organic compounds, which cannot be hardened or which harden only with difficulty,<sup>41</sup> or in a melt of solid hydrocarbons (chlorinated, nitrated or hydrogenated).<sup>42</sup> Among the organic substances used while molten as condensing media are rosin, copal, condensation products of mono- and polyvalent phenols or glycerol esters of phthalic acid, and nitrated, hydrogenated or chlorinated naphthalene as well as phenol-formaldehyde resins.<sup>43</sup>

In the production of molded articles from urea or its derivatives and solid polymerized formaldehyde in fused organic compounds,<sup>44</sup> catalysts added may function either in retarding or accelerating the reaction.<sup>45</sup> For retardation, i.e., to maintain the fluidity of the material for a longer time, basic catalysts (ammonia, calcium hydroxide, hexamethylenetetramine or sodium carbonate) are employed. Acid catalysts, including citric acid, acetic acid, hydrochloric acid and urea nitrate, as well as a number of neutral catalysts accelerate the solidification process, i.e., harden the resin.

Schmidt and Daniels<sup>46</sup> have suggested a molding composition prepared by grinding a mixture containing 110 parts of urea, 110 parts of paraformaldehyde, 150 parts of sulphite fiber and 50 parts of lithopone in a ball mill. The product is then transferred to differential sheeting rolls, where, on continued working, the resin-forming reaction sets in with a considerable rise in temperature. The water formed in the reaction is expelled as it is produced, and the operation is continued until the loss in weight (due to water expulsion) indicates the completion of the reaction. The resulting substance is a dry, sheeted mass, which, on being pulverized, is ready for molding. Additional plasticity is imparted by incorporating high-boiling solvents, e.g., diethyl or dibutyl tartrate or oxalate and halogenated naphthalene derivatives, with the material in the ball mill.

#### HARDENING CATALYSTS

In order to shorten the duration of the actual molding operation and hence lessen labor costs, Ellis<sup>47</sup> recommended the introduction of curing catalysts in the compositions employed. These catalysts may be direct acting (i.e., capable of accelerating the reaction at all times) or they may be latent (active mainly when a certain temperature is reached). Most of the white urea resin molding compositions are disintegrated by protracted heating, and hence the addition of hardening catalysts (especially the latent variety) by shortening the molding time tends to avoid the deterioration of the color and appearance of the article. To prepare

molding compositions, the initial urea-aldehyde reaction can be carried out in an alkaline medium, subsequent addition of acid controlling the hydrogen ion concentration. During the molding, an added latent catalyst (e.g., amine-hydrochlorides and sodium or barium ethylsulphate) liberates acid and effects the final hardening. Hardening catalysts may also be employed in urea resins containing cellulosic fillers. Thus, a secondary charge of wood flour is impregnated with the acid catalyst and added to the resin binder. Catalysts introduced in this manner do not come into active contact with the urea resin until the latter is molded. Protected in this manner, the acid is held in virtually an inactive state until the flow of the resin during hot pressing causes dissemination of the acid component with consequent increase in the rate of curing.

*Courtesy Modern Plastics*

Substances, exemplified by phthalic acid,  $\beta$ -bromohydrocinnamic acid and isodibromosuccinic anhydride which dissolve when the resin melts, producing acidity, were incorporated by Howald<sup>48</sup> together with plasticizers (e.g., natural or alkyd resins) in urea molding powders. In this way, 1 mol of urea was refluxed 30 minutes with 2.25 mols of formaldehyde to which triethanolamine had been added.<sup>49</sup> The mixture was partially evaporated, more urea added and evaporation completed. The ground product was mixed with a polybasic acid-polyhydric alcohol resin containing an excess of free acid, and sufficient urea was added to give the ratio 1 mol of urea to 1.5 or 2 mols of formaldehyde.

The water usually present under molding conditions is used, by Eaton,<sup>50</sup> to react with a neutral organic substance to liberate acid *in situ*, e.g. addition of 0.25-1 per cent of dimethyl oxalate is recommended. A small proportion (about 3 per cent) of a mixture of various plasticizers may be added to assist the flow during molding.<sup>51</sup>

<sup>51</sup> M. M. Eaton, British P. 358,075, 1930, to Pollopas, Ltd.; *Chem. Abs.*, 1933, 27, 436. French P. 718,094, 1931; *Chem. Abs.*, 1933, 27, 1531.

Salts of hexamethylenetetramine may be added as accelerators,<sup>53</sup> and a solid organic acid (oxalic acid) incorporated with the mass while the material is being ground. Plastic compositions containing an acid accelerator are said to be preserved without alteration by incorporating, in the composition, hexamethylene-tetramine in excess of the total amount of acid present.<sup>54</sup>

As an alternative to the process of grinding the dried polymerization product, the material may be obtained in finely divided form by spraying the solution against a current of warm air at 40-50°C.<sup>54</sup> Such a process applied to the hydrophile condensation product of less than two mols of formaldehyde with 1 mol of urea yields a product which may be mixed with ammonium sulphate to accelerate hot-pressing. According to Pollak and Kraus,<sup>55</sup> it is very desirable that molding compositions should have a low degree of polymerization and be free from excess formaldehyde. Premature polymerization may be brought about either by drying at too high a temperature, or by the action of excess of acid in the preparation of the resin. The amount of acid or acid salt used should therefore be rigidly restricted and drying is best performed *in vacuo*. Spray drying can be used to dehydrate the finely comminuted product. The deleterious effect of free formaldehyde is overcome by the addition to the molding powder of ammonium salts, e.g., 0.5-2 per cent of ammonium sulphate, in a dry state. The time occupied in the molding operation may also be cut down by carrying out only partial polymerization within the mold, followed by a more prolonged heating process outside the mold to complete curing.

A urea-formaldehyde product in the preliminary stage of its condensation is sometimes dissolved in a solvent (dichlorohydrin), mixed with a filler and converted to an insoluble form by heating.<sup>56</sup>

#### USE OF WATER TO INCREASE FLOW

A method of producing transparent plates from urea-formaldehyde condensation products was developed by Goldschmidt and Beuschel.<sup>57</sup> In this process, thin, dry plates of the condensation product are treated for a short time with a liquid or vapor not acting as a binder (e.g., with water or with a water-soluble organic liquid that is not a solvent for the condensation product). The plates are then superimposed and united by heat and pressure.

The function of water in increasing the flow properties of urea-formaldehyde resins is emphasized in the work of Landecker.<sup>58</sup> The urea-formaldehyde resins resemble protein-like masses such as casein, horn or glue in that they all show an excellent plasticity when molded with sufficient added water. Thus, a powdered urea-formaldehyde molding material acquires a satisfactory fluidity on the addition of about 5 per cent by weight of water. The resulting plasticity enables the moistened powder to flow under a pressure of less than 1000 pounds per square inch and allows the overflow to be rapidly squeezed out of the mold. This is considered to be advantageous since, according to Landecker, urea resins normally require a pressure of 4000 pounds per square inch for manufacturing even small and simple articles. In place of water, a salt that yields water of crystallization may be employed, and other liquids such as those which serve as plasticizers for natural albuminous substances

(e.g., alcohols, amines or ketones) are also used. Instead of adding water to the dried molding composition, the wet condensation mass may be dried on hot rollers until the proper moisture content (10-20 per cent) is obtained. The water-containing urea-aldehyde resin may be molded at 110° with a pressure of 700-1000 pounds per square inch.

Ellis<sup>80</sup> found that the flow of urea resin molding compositions could be improved by slightly moistening with water. The water is atomized into the pulverized material while the latter is being agitated. The resulting product is not of the best grade, however, and the process is not recommended for the production of high-quality articles.

The use of 5 per cent of water, alcohol, ketones or amines with powdered urea-aldehyde resins to increase the fluidity was suggested by other workers.<sup>80</sup> Fillers, pigments and glycerol or other moisture-absorbing substances may also be added. A similar treatment serves for thiourea resins.

#### MOLDING COMPOSITIONS WITH CELLULOSIC FILLERS

Although shaped articles made from clear, glass-like urea-formaldehyde condensation products are not likely to be permanent<sup>81</sup> (see Chapter 27), conditions are quite different when a substantial proportion of cellulose is present with the urea. There is definite indication of an affinity between urea resin condensates and cellulose. It is probable that between cellulose and urea resin there exists a combination explainable on the basis of secondary valence or covalence. So definite are the indications of chemical combination of the recognized type or of the various reactions resulting from covalence affinities that the author has given the term "urea-formaldehyde cellulosate" to the product obtained.<sup>81a</sup> It suffices to say that the compositions which contain a considerable proportion of cellulose incorporated with the urea-formaldehyde condensation products are permanent as compared with the clear glass products in which the cellulose is absent.

The cellulosic fillers may be used either in the crude form, as wood flour, or the purified type (paper, cotton flock or  $\alpha$ -cellulose in sheet form).<sup>82</sup> The urea-formaldehyde resin, as a syrup, should contain sufficient water to impregnate the cellulose fibers completely and is best added while hot. Impregnation is conveniently carried out by running the resin syrup into an evacuated vessel containing the cellulose and then applying 50-100 lb. pressure. The canals of the fibers are in this manner completely filled. For the preparation of molding compositions, the dried material should be ground fine, inorganic pigments being added at this stage.

Non-discoloring mold lubricants represented by zinc, magnesium or calcium stearates, to the extent of less than 1 per cent, may be incorporated during grinding, and the compositions molded under 1000-3000 lb. per square inch at 110-150°C. For white objects, the desirable maximum temperature is about 130°C., while 150°C. usually should not be exceeded owing to the risk of blistering. The tendency to blister is greatly reduced by cellulose, which acts as something more than a mere filler. Mechanically held water is well removed by the drying process. The water present within the mold, which may give rise to blistering, is produced by the condensation reactions constituting the curing step. Cellulosic materials, especially hydrocellulose, which may have become partially dehydrated during

<sup>80</sup> Carleton Ellis, U. S. P. 1,905,999, Apr. 25, 1933, to Ellis-Foster Co.; *Chem. Abs.*, 1933, 27, 3629.

<sup>81a</sup> G. Payras (*Rev. gén. mat. plastiques*, 1933, 9, 79; *Chem. Abs.*, 1933, 27, 2590) stated that cracks in articles made from urea-formaldehyde resins are caused by the presence of free acid, primarily.

<sup>82</sup> Briefly termed a *glucanure*.

<sup>80</sup> Carleton Ellis, U. S. P. 1,905,999, Apr. 25, 1933, to Ellis-Foster Co.; *Chem. Abs.*, 1933, 27, 3629.

drying, are able to take up a large part of this moisture thereby inhibiting blistering. Acid salts, such as sodium hydrogen sulphate, are active catalysts of the curing process, and may be incorporated in latent form as sodium ethyl sulphate which decomposes hydrolytically in the hot press. Translucency of the pressed product is promoted by thorough incorporation of the resin syrup with the cellu-

lose, and careful and complete drying. Mineral pigments should be absent<sup>62a</sup> for best results, as should more than a small percentage of mold lubricant. The use of high pressures during molding (2000-3000 lb.) is advantageous.

Cellulose-urea resins made in this manner are employed for a great variety of products; viz., molded articles and sheets, extruded rods and tubes and veneered stock. Resistance to water is enhanced by the incorporation of a proportion of thiourea, as little as 10 per cent having a marked effect.

<sup>62a</sup> A small proportion of a white pigment such as titanium oxide or lithopone is sometimes used in conjunction with a much larger proportion of cellulose, in making light-colored molded articles.

A valuable property of resins of this type is the possibility of making materials containing a relatively high proportion of cellulose by a two-stage process. Just sufficient cellulose may first be added to absorb completely the resin syrup, e.g., 40 parts of wood flour to 60 parts of resin solids, and this material is dried. The dried impregnated material is then ground with an additional quantity of unimpregnated cellulose, and as a result the finished molding composition may contain as little as 15 per cent of resin solids. In this manner, the prolonged drying of large masses of impregnated cellulose and possible difficulties from incomplete drying due to formation of incrustations are avoided. Moreover, curing catalysts

FIG. 99a.—A Typical Time-Pressure Chart (of a Urea Resin) Obtained with Apparatus Shown in Fig. 99. Graph indicates the pressure necessary to flow the thermosetting composition in various stages of cure.

may be added in disseminated form as impregnants of the secondarily added cellulose. Boric acid, phosphoric acid, phosphomolybdic acid and other inorganic acids, acid salts and non-volatile organic acids serve as catalysts for the purpose. The use of a well-dried secondary charge of cellulose is especially helpful in absorbing liberated water, assisting in avoidance of blistering. During the curing step, some solution or absorption of the cellulose occurs, since the ligneous structure appears to be largely destroyed. Products obtained from cedar-wood flour differ from those produced from pine or spruce woods.

As an example of the production of such compositions, 840 parts of urea are mixed while cold and refluxed for 10 minutes with 2400 parts of 37 per cent formaldehyde of  $p_H$  5.6. Next, 300 parts of thiourea are added, and the boiling continued for 20 minutes. The liquid is poured over 730 parts of wood flour, and the mass dried at 30-50°C. on Monel metal screens. The dried material is ground to pass a 40-mesh sieve, and then molded at 100-130°C. under 1500 lb. pressure, giving a light brown, translucent product.

Derivatives of cellulose (cellulose esters) were employed by Nash<sup>66</sup> as filling materials in the reaction of urea and solid polymers of formaldehyde. Cellulose acetate (32 parts) is admixed with 94 parts (by weight) of urea, 94 parts of paraformaldehyde and 100 parts of wood flour. After thorough mixing, the material is transferred to differential mixing rolls and sheeted. The resin formation takes place during this operation, after which the sheets are crushed and pulverized for use as a molding powder. Additional plasticity is imparted to the product by adding ethylene glycol, naphthalene or the di-alkyl esters of oxalic, tartaric or phthalic acid to the original mix. Other additions, including natural or synthetic resins, substances capable of reacting with uncombined formaldehyde, high-boiling organic compounds to increase the flexibility and materials that bind the water formed in the reaction, may be made.<sup>64</sup> The progress of the resin formation is retarded by ammonia, hexamethylenetetramine, calcium hydroxide and sodium carbonate, and is accelerated by acids or acid salts.<sup>65</sup> Lougovoy<sup>66</sup> used urea-aldehyde resins together with nitrocellulose and an organic solvent for molding.

#### VARIOUS APPLICATIONS OF UREA RESINS IN MOLDING

The urea-aldehyde resins have been applied in various other fields of hot-molding in addition to those already outlined. Waste wood, peat or lignin mixed with urea-aldehyde condensation products and molded under heat and pressure give insulating and coating materials.<sup>67</sup> Eisenmann and Bergmann<sup>68</sup> described a process for making electromagnet cores of high permeability by pressing a mixture of a urea-formaldehyde resin and iron powder (made by the thermal decomposition of iron carbonyl).

As an example, 4 kg. of iron powder are mixed in a kneading machine with 330 g. of an ethyl alcohol solution (36 per cent strength) of a condensation product of urea and formaldehyde, diluted with 800 g. of a mixture containing equal parts (by volume) of ethyl alcohol and benzene. After mixing, the solvent is entirely driven off by heating to about 80°C. *in vacuo*. The impregnated iron powder is formed into rings by a pressure of 7000 kg. per square centimeter in a mold. A core constructed from 3 such rings and provided with a single layer of winding has a specific gravity of 6.4 and a permeability ( $\mu$ ) of 35.2

Molds for producing printing surfaces, which may be used for casting type metal or for the production of rubber stamps or dies, are made from a mixture of urea-formaldehyde resin and graphite with other fillers (e.g., cellulose or asbestos).<sup>69</sup> A molding composition for making buttons is prepared by condensing urea with formaldehyde and adding an amount of starch or flour that is a multiple of the weight of urea used.<sup>70</sup> The mixture is pressed at room temperature or at a raised temperature. Other resins and softening agents (wool fat) may be added.

A method of preparing materials used in laminated products was described by Stockfisch.<sup>71</sup> The material consists of a paper base impregnated with urea-resin varnish. Calendered paper is run through the urea resin solution and then through

a tunnel system against a current of heated air which is controlled by an arrangement of steam pipes and baffle louvres (see Fig. 100). The paper passes through the varnish at a speed of 100 inches per minute with the tunnel temperature at 80°C. Squeezer rolls which force the varnish into the fibers control the accuracy of the resin content. A tower system embodying successive dips of the paper in the solution may also be employed. The impregnated papers are molded under heat and pressure.

Matches that can be repeatedly ignited by friction and extinguished were developed by Ringer<sup>73</sup> using a urea-aldehyde resin as a base. The slow-burning material has an igniting composition distributed in the resin base which is then molded into rods and coated with water glass. Pentamethylenediaminedisulphine (obtained from ammonium sulphide and formaldehyde) may be used with urea-formaldehyde condensation products in producing plastic-molding compositions.<sup>74</sup> Urea-formaldehyde resin compositions are also used in the hot molding of boxes.<sup>74</sup>

The problem of decorating urea ware (a term applied to molded urea-aldehyde products manufactured for domestic purposes) was studied by Froesé.<sup>75</sup> These

Courtesy Chemical and Metallurgical Engineering

FIG. 100.—Tunnel and Tower Systems Devised for the Impregnation of Fabrics or Paper with Urea Resin Varnishes. (H. E. Stockfish)

articles are normally decorated by applying to their surfaces decalcomanias or oil-pigments, which are easily effaced. Froesé found that the molded urea articles scorched when pressed against a sufficiently hot body and that the resin swelled if allowed to absorb intense heat. By using a properly shaped die at a temperature of about 650°C., any design can be burnt into the resin surface, leaving a bleached, raised border as an outline for the design.

A bonding composition is made by mixing coagulated rubber with a liquid urea-formaldehyde condensation product and heating (at a temperature below the hardening point of the urea resin) until the composition flows.<sup>76</sup> The rubber is thereby dispersed in the heat-hardenable liquid, and the composition serves as a bond for abrasive grains and other fillers. The recording layer of sound records may be made from a composition consisting of phenol and urea resins and not more than 20 per cent of inorganic and organic fillers in colloidal form (e.g., kaolin, steatite, graphite and nitrocellulose, or gelatin dissolved in glycerol).<sup>77</sup> Loudspeaker diaphragms are made by molding, under heat and pressure (about 800 kg. per sq. cm.), a solid polymer of formaldehyde and a urea in a broken or powdered form.<sup>78</sup>

A laminated pulp product described by Kienle and Scheiber<sup>79</sup> is produced by forming layers of interlocked fibers of wet paper pulp containing urea-formaldehyde resins. Fillers and pigments are added, and the material is dried and hot-molded.

Disintegrated cork can also be incorporated with up to 30 per cent of its weight of unhardened urea-aldehyde resin and molded under heat and pressure.<sup>80</sup> Other fillers including wood flour or lignin may be similarly impregnated and hardened in the press.<sup>81</sup> Catalysts, casein, horn, yeast and aldehydes are also added, the product being used as an electrical insulating material.

Vulcanized fiber can be made impermeable to water by treatment with a urea-formaldehyde resin.<sup>82</sup> Urea (30 parts) is dissolved in 100 parts of water, and vulcanized fiber is allowed to swell in this solution until it ceases to absorb any more of the liquid. The mass of vulcanized fiber, saturated with urea solution, is immersed in a 30 per cent solution of formaldehyde for 1-2 days. Catalysts (acids, bases or salts) may be added to the formaldehyde. The fiber is then dried and is heated at 90-95°C. for from a few hours up to several days, according to the dimensions of the articles

Keller<sup>83</sup> described the use of decorated sheets of fabric or paper impregnated with a viscous urea-formaldehyde resin solution for molding in or upon previously molded articles for the purpose of ornamentation. The impregnated material is

homogeneous molded objects. A single leaf of this material (or a few leaves pressed together) is said to be flexible and translucent. By using many layers, a tenacious, homogeneous, laminated material is obtained.

#### COMMERCIAL MOLDING COMPOSITIONS

A considerable use for urea resin molding compositions has been in the production of dish ware, including tableware of various sorts, and drinking cups (see Fig. 101); the relatively unbreakable quality of such moldings making them superior to glass for many purposes (see Fig. 102). On the other hand, unlike glass, such containers do not resist the high temperatures of a domestic oven sufficiently to be used for baking purposes. Urea resins are also extensively em-

<sup>1</sup>Courtesy American Cyanamid and Chemical Corp

FIG. 103.—Light Shades from Urea Resins; Forming Press in Background.

ployed in the button industry where their strength and resistance to washing make them superior to casein and vegetable ivory.<sup>87</sup> Since urea resins are odorless and possess chemical stability and mechanical strength, they are being used as caps and closures for jars and bottles.

The properties of commercial urea molding compositions may be illustrated by a consideration of the product known as Unyte.<sup>88</sup> This resin is sold in the form of granulated or powdered stock. Unyte is stable during storage, has an especially rapid curing time and can be manufactured in a variety of light-fast shades ranging from white through delicate pastel tints to black (see Fig. 103). During the molding of this product the flow can be easily controlled.

A urea-formaldehyde or urea-thiourea-formaldehyde molding powder known as "Beetle"<sup>88a</sup> is used in the manufacture of dishes, cups, a wide variety of household articles, automobile hardware and plumbing and electrical fixtures.<sup>89</sup> From this material molded articles can be made possessing light colors and an attractive

<sup>87</sup> Carleton Ellis, *Ind. Eng. Chem.*, 1934, 26, 38.

<sup>88</sup> Unyte is a product of the Unyte Corporation. See *Plastics and Molded Products*, 1932, 8, 76. See also *Chem. Met. Eng.*, 1935, 42, 43.

<sup>88a</sup> A product of Synthetic Plastics Co.

<sup>89</sup> *Molded Products*, 1929, 5, 95. See also A. C. Blackall, *Plastics*, 1927, 3, 606; 1928, 4, 200.

translucent appearance. The material can be formed into very thin layers and shapes. Special precautions must be taken to exclude dust during processing, and, in the case of powders containing thiourea, staining of molds must be avoided. Thiourea stock is molded in stainless steel or chromium-plated molds at 140-145°C. under pressures varying from 1500 to 3000 pounds per square inch. The curing time is usually 3-7 minutes, from 50 to 100 per cent longer than the phenolic molding compositions. The specific gravity of the molded product is reported to be 1.49

FIG. 104.—  
Chime Housing Molded from  
Beetle Urea Resin.

*Courtesy Modern Plastics*

and the tensile strength 5000-6000 lb. per square inch. Since the products are resistant to corrosion, one suggested use is as fittings in steamships, where attack by salt spray normally presents a serious problem.

Another molding composition of the urea-formaldehyde type is known as "Plaskon."<sup>90</sup> This material is unaffected by alcohol, acetone, oils or other common solvents, and the water absorption at 20°C. is 0.07-0.86 per cent in 24 hours. It is moderately resistant to cold, dilute acids, but is attacked by hot or concentrated acids. It also resists cold, dilute alkalies and hot, very dilute alkalies (soap, borax and cleaners). The specific gravity of the product is 1.43 and the dielectric strength (puncture) is 300-400 volts per mil.

A molding composition was prepared, by Pollak and Ripper,<sup>91</sup> by incorporating

<sup>90</sup> A. M. Howald, *Chem. Met. Eng.*, 1931, 38, 583. Plaskon is made by Toledo Synthetic Products, Inc. See also *Chem. Met. Eng.*, 1932, 39, 654.

<sup>91</sup> K. Ripper, U. S. P. 1,625,283, April 19, 1927, to F. Pollak; *Brit. Chem. Abs. B*, 1927, 532.

the viscous initial condensate of urea, thiourea and formaldehyde with fibrous fillers and pigments. The resulting material is hot-pressed at pressures of 150-300 kg. per square centimeter and given an additional air or vacuum drying.

#### RECOVERY OF SCRAP RESIN

The recovery of usable resin from the waste material of a molding plant or from splinters and borings obtained in the working of cured resin articles is an important economic factor especially in countries producing much turnery ware. The hardened material may be made soluble<sup>52</sup> by heating under pressure with more than an equal weight of formaldehyde solution at 120°C. for 2-3 hours. A thick solution is thereby obtained, which is diluted and boiled with a further quantity of urea, and subsequently processed as new material.

The cured resin may also be heated with aldehyde in the presence of acids,<sup>53</sup> or heated with the intermediate condensation product still containing free formaldehyde. It is also stated to be possible to mix the finely comminuted scrap material directly with formaldehyde and to use the product as a molding powder.

Ripper<sup>54</sup> described the use of mineral acids for resin recovery. The finely divided cured resin, boiled with 10 per cent hydrochloric or nitric acid, passes readily into solution, and on cooling or dilution is thrown down as a bulky precipitate which may be separated and dried. This powder is then brought into solution by formaldehyde or by mechanical dispersion in water with a colloid mill. The solutions are utilized as varnishes and impregnants, while the recovered powder is employed as a filling agent for the urea-formaldehyde resins made in the usual way.<sup>55</sup> Used for this purpose, resins are obtained from which water is expelled more readily, and which are said to harden faster than with unmixed material. Ammonium salts, which react with liberated formaldehyde and set free acid, may also be used as solubilizing agents, as may acid chlorides and acid salts. The solubilizing agents need be present in only limited quantity, as solution of the material is not required to be complete.<sup>56</sup> Thus, comminuted, cured resin can be merely swelled with hydrochloric acid and converted into a homogeneous material with heat and pressure.

## Chapter 29

### Urea Resins

#### III. Coating Compositions

Considering the preparation of lacquers from urea resins, it should be borne in mind that during the earliest stages of the urea-formaldehyde condensation the products are soluble in water or the formalin solution employed. The reaction product is at that stage, therefore, a hydrophilic colloid. On further condensation, however, the hydrophile becomes a hydrophobe and hence is insoluble in water.

For a number of purposes, urea resins may be used in the hydrophile stage, i.e., while still soluble in water, and, applied in this way, an inexpensive vehicle for the distribution of the condensation material is at hand. Water-soluble products are not desired, however, in a considerable number of applications where resins are employed, and the aim has been to produce resins which are soluble in organic solvents. This has been done, but, unfortunately, most of the effective solvents (such as the chlorohydrins) are costly.<sup>1</sup>

Another difficulty presenting itself is the tendency for urea resins in a lower stage of condensation to become converted gradually and spontaneously to a more highly condensed substance, so that a product which at one time is soluble in a given medium will later be found insoluble. Since the condensation of urea resins is usually accompanied by the liberation of small proportions of water, there is a tendency for the coatings to disintegrate long after they have dried. This may lead to the formation of fissures and to the disfigurement of the surface. Coatings which initially are bright and glossy may become dull and lusterless by the action of atmospheric moisture, if the stage of condensation of the material in the coating as initially applied is unduly low.

To improve the solubility of well-condensed urea resins in organic solvents and also to prevent the progress of further condensation after application, one development of manufacture comprises reacting urea and formaldehyde in the presence of an alcohol, butanol being particularly recommended, with the object of having the alcohol unite in the resin and confer solubility and stability. The results in this direction have been very promising, and lacquer compositions prepared in this manner have actually been brought on the market. Solid resins which are soluble in alcoholic solvents also are available.

#### UREA RESIN COATINGS

Aqueous solutions of the primary condensation products of urea and formaldehyde are colorless and can be made in various concentrations and viscosities. They show the typical properties of sols of highly solvated, hydrophilic colloids and have been suggested for various uses, including water-varnishes, adhesives and binding, impregnating and stiffening agents.

<sup>1</sup> See *Synthetic and Applied Finishes*, 1933, 3, 79.

A neutral solution of such a condensate was suggested as a lacquer or varnish by Ellis.<sup>2</sup> The solution is prepared by allowing 20 parts by weight of urea to react with 54 parts of formalin in the presence of 0.4 part of sodium hydroxide dissolved in an equal weight of water. As reaction proceeds the mixture eventually becomes turbid, and further interaction is checked by adding acid until the solution is substantially neutral. Glycerol, casein, gelatin, Irish moss, algin or pigments may be added. Applied to a surface, the solution dries and forms a varnish.

Ripper,<sup>3</sup> among others (see Chapter 28), used controlled hydrogen-ion concentrations as a means of obtaining urea resins for lacquer production. Thus, 30 parts by weight of urea are mixed with 100 parts of neutral 30 per cent formalin and heated in a boiler fitted with a reflux condenser. After a short time, 5 parts of boric acid dissolved in a little water are added, and the refluxing is continued for 6-7 hours. On standing in the cold for several hours longer, two layers are found to separate, the upper one being removed. The gel forming the lower layer is washed repeatedly with water and then dissolved in a non-aqueous solvent (epichlorohydrin). Mixed with softening agents, this lacquer solution gives a coating which is said to be insensitive to the action of water.

By incorporating water-soluble alginates (sodium alginate) with water-soluble urea- or thiourea-formaldehyde resins and an accelerator (e.g., acid potassium sulphate), Lefebure<sup>4</sup> obtained products of use as varnish stains, distemper paints and as impregnating agents for fiber boards. A colored urea resin lacquer is used for coatings on electric light bulbs.<sup>5</sup> The resin and dyes are applied to the bulbs by dipping, and the coating is hardened by the normal heat of the lamp.

Insoluble urea-formaldehyde products may be made soluble by heating with an excess of formaldehyde under pressure at a temperature above 100°C.<sup>6</sup> A suspension of the powdered resin in water or organic liquids can be applied to surfaces as a coating composition which is then dried and hardened by heat and pressure.<sup>7</sup> Hofer and Schmid<sup>8</sup> suggested the use of urea- or thiourea-formaldehyde resins together with a pigment for the production of a light-fast colored glaze on cement or tiles. A urea-thiourea-formaldehyde condensation product containing ammonium nitrate as hardening agent is stated to provide a waterproof glaze. Sodium phosphate was added as an accelerator to a thin paste (formed by heating urea, paraform and water at 90°C.) by Keller and Taylor<sup>9</sup> preparatory to forming a urea-formaldehyde varnish. According to Stoll,<sup>10</sup> natural or artificial stone and pottery may be coated with urea-formaldehyde resins in conjunction with a phenol-formaldehyde product and pigments. A temperature of 130°C. can be employed for hardening such coatings.<sup>11</sup> Another coating composition for use on wood,

<sup>11</sup> German P. 550,319, 1928, to Mathys & Schaaf; *Chem. Abs.*, 1932, 26, 4151.

metals and cement consists of finely divided casein, urea, hexamethylenetetramine, lime and pigments.<sup>12</sup>

Dissolved intermediate condensates of the urea-formaldehyde reaction may be mixed with colloidal or semicolloidal substances obtained by the polymerization of unsaturated compounds of the type of vinyl esters, acrolein and itaconic acid. When modified by such additions, the resin is reported to be applicable to the manufacture of varnishes, films, artificial silk and molded articles.<sup>13</sup>

Natural resins can be blended with urea-formaldehyde-salicylic acid lacquers, according to Belfit.<sup>14</sup> The resins are first dissolved in a solvent, the nature of which is determined by the kind of resin concerned. Denatured alcohol can be used for shellac, and a mixture of denatured alcohol and butyl acetate serves as a solvent for mastic. Among the natural substances that may be employed are

*Courtesy Unyte Corporation*

FIG. 105.—Part of Control Laboratory in a Plant Manufacturing Urea Resin Molding Compositions.

kauri, sandarac, guaiac, dammar, camphor, Zanzibar, elemi, rosin and ester gum. These lacquers can be applied to metals (e.g., brass or gold).

A resin from thiourea, or from a mixture of thiourea and urea, and formaldehyde mixed with a hardening agent, e.g., a pasty mixture of paraformaldehyde and formaldehyde solution, is used with a solvent (ethyl lactate, ethylene glycol or the ethyl ether of ethylene glycol) to form a varnish.<sup>15</sup> Bender<sup>16</sup> found that a urea- or thiourea-formaldehyde resin in the initial stage of its condensation and dissolved in a high-boiling solvent could be advanced toward a more highly condensed (infusible) stage by heating. An infusible resin is obtained thus as a colloidal suspension that can be directly applied as a varnish. A varnish yielding flexible films and prepared by the addition of a plasticizer (butyl phthalate) to a urea-aldehyde resin was described by Turkington.<sup>17</sup> According to Bender<sup>18</sup> such a plasticized resin gives a firmly adherent coating with a glossy surface resistant to

moisture and heat. If the coating is applied to a viscose base, a product of high dielectric strength is obtained. Another method of forming a varnish is that of condensing thiourea (with or without additions of urea) and anhydrous formaldehyde in the presence of a monoalkyl ether of ethylene glycol and an alkyl lactate.<sup>19</sup> The proportions of the components are chosen so as to give a potentially reactive resin.

Christensen<sup>20</sup> described a composition for use as a varnish, sizing or paint, prepared by mixing "leather gum" and shellac with urea and aldol, acetaldehyde or paraldehyde. To prepare the "leather gum," leather scrap is treated for 6-24 hours with a 0.5-2 per cent solution of hydrochloric acid and removed to an open vessel containing water where it is boiled for 0.5-3 hours. The leather, now consisting almost entirely of fibrous protein material, becomes disintegrated and settles in the form of a heavy brown gum which is dried, and ground.

The surface of metals or other materials may be coated with lacquers prepared from urea resins and varying proportions of silicon or an acid-proof, heavy-metal silicide.<sup>21</sup> A basic, phenol-formaldehyde coating is usually first applied, and the thick covering layer is hardened.

#### FILM-HARDENING AGENTS

Belfit<sup>22</sup> investigated a group of compounds, including salicylic acid, gallic acid and hydroxynaphthoic acids, which when added to the resin solution increase the resistance of the final coating to solvents, sulphur compounds and other corrosive agents.

As an example, 400 g. of urea are dissolved in 2000 cc. of 40 per cent formaldehyde solution, and the mixture is heated on a steam bath until 40-60 per cent by weight has been evaporated. Water is then added to increase the weight to 75 per cent of its initial value. The solution is filtered to remove insoluble matter, and to 81 cc. of the solution are added 50 cc. of denatured alcohol, 42 cc. of butyl alcohol, 7 cc. of ethyl lactate and 5 g. of salicylic acid. The solvents in such a lacquer may be evaporated off in the air or by baking at 100°C. for a short period. The final hardening of the film is accomplished by heating at 130-135°C. for about 20 minutes. After hardening the first film, a second coating may be applied, as the solvents of the lacquer will not dissolve the hardened film. A thin layer of this lacquer is said to resist the attacks of sulphur compounds, alcohol, air, moisture and salt spray.

Various other ingredients may be incorporated in this type of lacquer. Thus, castor oil (in an amount equal to 2.5 per cent of the total proportion of solids present) serves as a plasticizer, increasing the pliability of the film and rendering it more impervious to liquids. One part of a lacquer consisting of 81 cc. of a urea resin solution, 50 cc. of denatured alcohol, 42 cc. of butyl alcohol, 7 cc. of ethyl lactate and 20 g. of salicylic acid may be admixed with 2 parts of a cellulose lacquer. The resulting composition is applied by spraying or dipping and is hardened by baking at 135°C.

The application of film-hardening agents (such as salicylic acid) may be extended to thiourea resins and to resins containing urea derivatives such as benzoyl-urea, acetylurea, cyanamide and guanidine.<sup>23</sup> Such modified urea-aldehyde resins lend themselves to the production of various types of lacquer compositions which are intended for protecting the surfaces of non-ferrous metals, including silver, nickel, copper, brass, aluminum and various alloys.

<sup>23</sup> R. W. Belfit, U. S. P. 1,898,754 and 1,898,755, Feb. 21, 1933, to Scovill Mfg. Co.; *Chem. Abs.*, 1933, 27, 2831. Canadian P. 304,615, 1930; *Chem. Abs.*, 1930, 24, 6042.

Clear films, according to Belfit, are obtained by blending Bakelite lacquers with urea resin lacquers. A blended lacquer of this type may be composed of 7.5 gallons of Cellosolve (glycol monoethyl ether) containing 10 ounces of nitrocellulose per gallon, 14 gallons of denatured alcohol, 10 gallons of butyl alcohol, 10 gallons of ethyl lactate, 7.5 gallons of urea-formaldehyde-salicylic acid lacquer and 1 gallon of Bakelite lacquer.

Films of urea resins can be rapidly hardened by treatment with gaseous sulphur dioxide or solutions of the latter.<sup>24</sup> Aqueous solutions of sulphur dioxide frequently lead to surface opacity, but this may be overcome by using non-aqueous solutions or the gas itself. As an example, 6 kg. of urea, 200 g. of monosodium phosphate and 50 g. of disodium phosphate are dissolved in 5 l. of water and heated. The solution is slowly added to 18.75 kg. of a 32 per cent formaldehyde solution; and, after evaporation, the viscous condensation product is poured onto a smooth plate and exposed to an atmosphere of sulphur dioxide. After some minutes a hard superficial layer, which is no longer adhesive, has been formed. Other volatile acids or acid anhydrides can be employed.<sup>25</sup> The hardening effect varies with the kind and concentration of acid agent used.

#### UREA RESINS WITH NITROCELLULOSE

Urea-aldehyde condensation products have been employed in nitrocellulose lacquer compositions.<sup>26</sup> Some of their general properties<sup>27</sup> in this connection are illustrated by the "Plastopals,"<sup>28</sup> which are urea resins made in the presence of organic solvents. These substances are neutral, very pale in color and are light-fast.<sup>29</sup> They are soluble in alcohols, in glycol ethers (methyl, ethyl or butyl glycol), in cyclohexanone, diacetone alcohol and in mixed ester solvents. The Plastopals are insoluble in pure esters, ether esters, aliphatic ketones and aromatic hydrocarbons. They can be mixed with both ester-soluble and alcohol-soluble collodion cottons. In admixture with nitrocellulose, additions of castor oil may be made to the resins.

On heating for long periods the Plastopals become insoluble. Resins of this type incorporated with nitrocellulose are made insoluble more readily, being hardened in 24-48 hours at temperatures greater than 60°C. or in some weeks at room-temperature. The films obtained from such resins are slightly affected by water; but if nitrocellulose is a part of the composition, the coatings show good weather resistance. These products are very similar in many of their properties to ordinary shellac, although they are superior in their fastness to light, possess a more nearly water-white color and are completely homogeneous. They are useful in nitrocellulose lacquers containing alcohol as the main solvent and as a component of all types of wood lacquers. In contrast to the much-used spirit varnish resins, the urea resins give polishing lacquers that do not smear on rubbing with media containing mineral oil.

Resins of this general type may be prepared by the condensation of urea and formaldehyde in ethylene chlorohydrin. To 50 parts of a 50 per cent solution of the urea condensate in ethylene chlorohydrin is added a solution containing 3 parts of acetyl cellulose and 1 part of camphor in 50 parts of the same solvent.<sup>30</sup> When the solvent

is evaporated from this lacquer, a clear film remains. A lacquer can be prepared by dissolving 5 parts of cellulose nitrate in 50 parts of a 30 per cent solution of a urea-formaldehyde resin in glycol monoacetate. The diethers of ethylene glycol are also used as solvents in these preparations.<sup>41</sup>

Using alcohols as solvents, condensation under mild conditions leads to the formation and separation of crystalline compounds, more highly condensed than dimethylolurea, as has already been discussed (see Chapter 26).<sup>42</sup> These substances may be subjected to further condensation in non-aqueous solution, either by fusion or by heating under pressure in alcoholic solution, in the absence of condensing agents, to make a lacquer.

Resins of similar type are prepared also from dimethylolurea, by suspending the substance in its own weight of methanol and boiling for 5-10 minutes with about 0.5 per cent of 1 *N* alcoholic hydrochloric acid. The mix is neutralized and filtered, and a crystalline product separates in colorless needles melting at 100-102°C. If 148 parts of this substance be heated with 175 parts of absolute methanol for half an hour at 80°C. under pressure, with an addition of 5 parts of sodium dihydrogen phosphate, condensation proceeds further. The mixture is neutralized with lime and filtered, yielding a lacquer containing 35-40 per cent of the condensation product.

The substances obtained by condensation in alcoholic solution are precipitated<sup>43</sup> by the addition of hydrocarbons, ethers (e.g., dioxane, anisole or glycol dialkyl ethers) and other non-hydroxylic compounds. The precipitated condensation product is freed from adhering solvents by washing with volatile inert liquids of the types named. The dried, powdered products are soluble in many hydroxylic solvents, in aldehydes and ketones (cyclohexanone) or in ester solvents, e.g., butyl acetate. Substances produced by condensation in the lower alcohols (ethanol or glycol) are somewhat sensitive to water, whereas the products from reaction mixtures of higher monohydric alcohols, especially amyl and benzyl alcohols, are practically unaffected by water, but are not readily freed from the high-boiling solvent. If, however, the washed condensation product, e.g., that from amyl alcohol, is dissolved in a volatile solvent (glycol monomethyl ether), there is obtained a water-resistant lacquer which does not retain the original, non-volatile solvent.

As an example of the application of the process to lacquer preparations, 50 parts of a 40 per cent solution of a condensation product of dimethylolthiourea in benzyl alcohol are stirred with 500 parts of ether. The precipitated solid is agitated several times with ether, filtered and dried *in vacuo* at 50°C. The powdered product may then be dissolved in an equal weight of glycol monomethyl ether at 80°C., and diluted with ethanol to form a lacquer which gives clear water-resistant coatings. Cellulose esters and softening agents may be incorporated. By heating 360 parts of dimethylolurea suspended in 500 parts of dioxane to 85°C. in the presence of 4 parts of oxalic acid, a higher condensation product is obtained.<sup>44</sup>

Lauter<sup>45</sup> concluded that the waterproof properties and the flexibility of urea-formaldehyde resins would be enhanced by carrying out the condensation in the presence of glycerol or other polyhydric alcohols. Not more than 1.2 mols of glycerol, according to Lauter, should be added per mol of urea, with one additional molar proportion of formaldehyde for each mol of glycerol.

<sup>44</sup> This material, after washing and drying, may be molded, forming transparent, homogeneous masses.

<sup>45</sup> F. Lauter, U. S. P. 1,633,337, June 21, 1927, to Röhm & Haas Co.; *Chem. Abs.*, 1927, 21, 2568. British P. 256,248, 1926; *Brit. Chem. Abs. B*, 1928, 165.

Lacquers<sup>36</sup> may be obtained by carrying out the condensation in the presence of halogenated aromatic alcohols or of glycols partially esterified with halogenated aryl groups, but containing unsubstituted hydroxyl radicals. Appropriate solvents are *o*-chlorobenzyl alcohol, glycol monobromophenyl ether and glycol bromosalicylate, using acetic acid or oxalic acid as condensing agents.

The condensation of urea (or thiourea) and formaldehyde or its polymers at a temperature of 100-160°C. and in the presence of a hydroxylated solvent (butanol or isobutanol) as discussed previously, furnishes substances that can be used with cellulose esters or ethers and oils in the production of lacquers.<sup>37</sup>

Thus, Neubauer<sup>38</sup> described the preparation of lacquers and films by dissolving 10 parts of a 50 per cent methyl alcohol solution of such a condensation product of urea and formaldehyde in 40 parts of a 20 per cent nitrocellulose solution and adding 20 parts of hexyl acetate together with 20 parts of benzene. The clear, viscous solution obtained furnishes smooth and glossy coatings when sprayed on leather, glass, paper, wood and textiles. Replacing the hexyl acetate and benzene with 20 parts of ethylene glycol monoethyl ether, 24 parts of cyclohexanol, 8 parts of butyl alcohol and 8 parts of propyl alcohol, a lacquer which forms smooth, supple and firmly adherent coatings is compounded.

Pungs and Eisenmann<sup>39</sup> employed a urea resin condensed in butyl alcohol for varnishes together with nitrocellulose and a drying oil varnish. As an example, 18 parts of a 43 per cent solution of a urea resin in isobutyl alcohol are mixed with a solution of 3 parts of nitrocellulose and 6 parts of an oil varnish consisting of 66 parts of melted Congo copal, 33 parts of boiled linseed oil and 1 part of cobalt resinate all dissolved in 10 parts of butyl acetate, 25 parts of ethyl alcohol and 35 parts of toluene. To this composition, 6 parts of an oily fraction boiling at 150-190°C. obtained by the catalytic hydrogenation of oxides of carbon are added. The resulting lacquer gives clear, hard films.

Vegetable or animal oils, including linseed oil, castor oil and cod-liver oil, that have been pretreated with oxidizing gases at 140-180°C. can be incorporated with urea-formaldehyde resins and nitrocellulose to form lacquers.<sup>40</sup> The oxidation conditions must be controlled to insure the formation of a viscous oil and not a jelly. The odor of the oxidation product is removed, or at least improved, by treatment with hydrogen and a hydrogenating catalyst, care being taken to keep the products from solidifying. The hydrogenation of the oil may be performed before the oxidation treatment. The added oils and the use of relatively large proportions of nitrocellulose improve the water-resistance, flexibility and the adhesive properties of the lacquer coating.

To illustrate the preparation, 140 parts of a 43 per cent isobutyl alcohol solution of the condensation product are mixed with a solution of 60 parts of nitrocellulose and 45 parts of shark oil (pretreated with oxidizing gases) in 100 parts of butyl acetate, 200 parts of ethyl lactate, 300 parts of ethyl alcohol and 300 parts of toluene. The resulting composition is a clear, transparent lacquer. Solid urea-formaldehyde condensation products may be treated with organic solvents to separate the solid, insoluble part from the viscous, soluble portion.<sup>40a</sup> The solid, brittle component is used for

lacquers and artificial masses, and the viscous part is used as glue or as a softener for cellulose.

Lougovoy<sup>41</sup> also prepared lacquers by mixing urea-formaldehyde condensates with nitrocellulose. Urea (10 parts) and formalin (60 parts) are refluxed in an approximately neutral medium for 15-60 minutes giving a syrupy product which is diluted with an equal volume of acetone. Acetone will mix in the cold with many urea-formaldehyde syrups. Alcohol, however, is not as miscible and is best added to the hot condensate. Furfural and also phenol can be employed as solvents for the resin syrup. To 100 parts of the acetone solution of the urea condensate 5-50 parts of nitrocellulose may be added. The nitrocellulose-urea solutions give light-colored coatings when applied to wood or other surfaces.

Electrical insulating materials for use as coatings are obtained by incorporating castor oil, nitrocellulose and rosin with a urea-formaldehyde resin.<sup>42</sup> For example, 33 parts of a 46 per cent solution of urea resin in butyl alcohol are mixed with a solution of 15 parts of nitrocellulose, 30 parts of blown castor oil and 6 parts of rosin in 25 parts of butyl acetate, 75 parts of ethyl alcohol and 75 parts of toluene. These coatings are adherent, elastic and durable after drying for 8 hours at 75°C. They resist many mineral acids and are unattacked by transformer oils at high temperatures.

Only polymerization products of diolefins (e.g., butadiene), polymerized without the aid of alkali metals, have also been suggested for incorporation with cellulose esters or ethers and urea-formaldehyde resins in the manufacture of coating compositions.<sup>43</sup>

Eisenmann and Kollman,<sup>44</sup> developed a method of producing lacquers from the condensation products of urea and related compounds with formaldehyde by heating these products suspended in an anhydrous solvent with a substance capable of taking up water. Thus, 150 parts of dimethylolurea and 50 parts of dimethylolthiourea are suspended in 250 parts of benzyl alcohol. While stirring, the mixture is heated to 110°C. with 36 parts of anhydrous calcium nitrate and kept at this temperature for 2 hours. After removing the calcium nitrate a clear solution is obtained which may be mixed with nitrocellulose, forming a coating with a high luster. The condensation may also be carried out with hydrochloric acid in hot ethyl alcohol solution.<sup>45</sup> Sodium acetate is added and the alcohol evaporated, giving a resin which hardens to a transparent material on heating. Using isobutyl alcohol as a medium, Pungs and Eisenmann<sup>46</sup> heated 200 parts of dimethylolurea in an autoclave to 135°C. and at a pressure of 8 atmospheres. The clear solution obtained by cooling gave a solid condensation product after steam distillation.

The condensation of dimethylolurea (or of dimethylolurea ethers) to vitreous masses or lacquers may conveniently be effected by passing a buffered urea-formaldehyde solution continuously through a system of tubes at 100°C.<sup>47</sup> discharging into a vacuum drier. If, instead of an aqueous vehicle, alcoholic media (e.g., isobutanol) be employed, the acidic buffering salts (usually primary and secondary sodium phosphate) are neutralized with sodium carbonate. The solutions are clarified in a centrifuge and may then be used as lacquers.

Treatment of dimethylolurea with alkaline reagents (suspended or dissolved in phenolic solvents to absorb disengaged formaldehyde)<sup>48</sup> yields partially dehydrated products of higher molecular weight, which may then be resinified by condensation in hot acid solution.

Coating compositions for wood, natural or imitation leather, brickwork, asbestos, paper or textiles can be prepared by emulsifying solutions of cellulose esters, in water-insoluble organic solvents, with aqueous solutions of urea-formaldehyde resins, softening agents, other emulsifying or wetting agents, coloring materials and extending agents.<sup>49</sup> Threads or films made from mixtures of cellulose esters or ethers and urea resins are said to possess greater strength than the purely cellulosic material.<sup>50</sup> The condensation of toluene sulphonamide with formaldehyde and urea gives a product that may be mixed with cellulose compositions in the manufacture of films, filaments and coating compositions.<sup>51</sup>

## Chapter 30

### Urea Resins

#### IV. Miscellaneous Uses

The applications of urea resins in coating compositions, in molding powders and in attempts to prepare organic glass have been discussed,<sup>1</sup> but there remain various special and miscellaneous uses which will be treated in this chapter. Among these diverse adaptations are the treatment of textiles with urea resins for the purpose of conferring crease-resistant properties, the production of adhesives, the impregnation of wood, paper and other cellulosic materials, the manufacture of safety glass, and other applications.

##### TREATMENT OF TEXTILE MATERIALS

The urea-formaldehyde resins have found considerable application in the treatment of textile materials to render them crease-proof.<sup>2</sup> Clayton,<sup>3</sup> in discussing the use of synthetic resins for conferring anti-crease properties on textiles, drew attention to the non-creasing attributes of good quality woolen fabrics. Cotton goods, however, crumple readily since the cotton fibers are relatively plastic. Linen and artificial silk behave like cotton in this respect. After treatment with synthetic resins, woven and knitted cellulose fabrics approach wool or silk in their resistance to and recovery from creasing, without losing their draping qualities or handling simplicity. Similarly treated regenerated cellulose possesses an increased dry strength and a greatly increased wet strength. The weight of the treated material is increased by an average of 15 per cent. The anti-crease process reduces the textile's tendency to slip and to shrink (when laundered). The extensibility of artificial silk is also reduced; and, thus, the many forms of distortion to which this material is especially susceptible are less likely to occur.

The general method of processing the fabrics is about as follows.<sup>4</sup> The fibers of cotton or rayon material are treated with alkali until the cellulose is considerably swollen, the alkali is washed out, and the wet material is then impregnated with the resin components. Phenol-formaldehyde resins, as well as those from urea and formaldehyde, can be used in treating the cloth. If urea resin is employed, 1 part of urea and 2 parts of a 40 per cent formaldehyde solution are mixed, made slightly alkaline with hexamethylenetetramine or sodium hydroxide, boiled under reflux for 3-5 minutes and cooled quickly. The mixture (3 parts) is diluted with 1 part of water, and 0.5-0.75 per cent of acetic acid or an equivalent amount of any weak acid is added.

The squeezed, damp mercerized cloth is run, with repeated nippings between rollers,

through the resin mixture. The fabric is then dried at a low temperature, and the resin is made insoluble by heating at 180°C. The acetic acid acts as a catalyst for the resin condensation which occurs on the fibers. It is important that an acid and not an alkali be used as catalyst at this stage; for with an alkaline reagent, the non-crush effect becomes less resistant to washing. When phenol-formaldehyde resins are substituted for those from urea and formaldehyde,<sup>6</sup> acid or alkaline catalysts can be employed in the condensation. Too much resin must not be added to the fabric since this would cause stiffness and actually promote the creasability of the material.

In order to render cotton or rayon fabrics less susceptible to creasing and wrinkling while still preserving their suppleness, Zänker<sup>6</sup> applied a water-soluble urea-formaldehyde resin together with a metallic salt (acetates or other salts of zinc, aluminum, zirconium, tin or titanium). After impregnation in a solution of these components, the fiber is heated, resulting in the formation of an insoluble resin and a water-soluble inorganic compound. The proportions of resin and metallic compound used are too small to cause appreciable stiffness.

Horsfall and Lawrie<sup>7</sup> found that urea-formaldehyde resins greatly reduce or prevent the deterioration of animal fibers and fur by acid or alkaline media. Such protective action is needed in wool scouring and the dyeing of wool or silk with vat colors. Thus, unscoured wool is treated for 0.5-0.75 hour at 45-50°C. in a bath containing 10 per cent by weight of sodium carbonate (calculated on the weight of the wool) and 5 per cent of dimethylolurea. The wool is sufficiently scoured in this manner without suffering damage (e.g., tendering or loss of elasticity) from the injurious action of the alkali.

Cotton, silk, artificial silk or fabrics made from such materials may be treated with aqueous thiourea-formaldehyde resin solutions, and the condensation of the resin completed on the fiber by an acid condensing agent (oxalic acid).<sup>8</sup> The final condensation is carried out at 120-140°C., whereby the resin is made insoluble and a stiffening effect is obtained in the fabric. The impregnating solution also contains fillers including starch, gums and China clay. The quality of cloth and thread is improved, according to Syôji,<sup>9</sup> by similar means. The material is treated at 80°C. with a water-soluble urea-formaldehyde condensation product and dilute acid (0.3 per cent sulphuric acid) is applied; after which the textile is washed with water and dried.

Pollak<sup>10</sup> employed urea-formaldehyde resins for stiffening felt hats and paper. The raw hats are stretched on wooden blocks or models and impregnated with a solution containing from 5-10 per cent of the resin. Then they are treated with dry steam, until the odor of formaldehyde has decreased considerably, and are smoothed with a hot iron. Writing papers are similarly stiffened with a colorless and transparent coating.

Urea-formaldehyde resins, according to Heuck and Esselmann,<sup>11</sup> are able to reduce the swelling-capacity of hydrated cellulose, hence treatment with urea

resins increases the strength of viscose in the wet state. Viscose is soaked in a solution containing 40 parts of dimethylolurea and 0.4 part of sodium phosphate in 1000 cc., and is then dried for 24 hours at 110-120°C. to convert the resin to the insoluble form. During the impregnation, a solvent miscible with water, a softener and a wetting agent may also be added to the bath. Natural or artificial textile fibers can be given an uncrushable finish by the use of urea-formaldehyde resins condensed with alkalies.<sup>12</sup>

FIG. 106.—Pebble Mill, Jacketed with Silent Chain and Motor Drive, Used for Grinding Urea Plastics.

Urea resins have been used with glass particles, metal or pearl dust, mica flakes, wool and cotton in producing ornamented materials.<sup>13</sup> Chaloupka<sup>14</sup> also described a method of ornamenting silk, gauze and other pliable fabrics with spaced, globular deposits of the hard, insoluble, final condensation product of urea and formaldehyde. The local effects produced by employing urea resins during the processing of the material are varied and numerous.<sup>15</sup>

Thus, if acetate silk is printed with a paste containing gum arabic and 5 per cent of dimethylolurea and steamed or hung in the air, damask effects are obtained, since the printed spots are dull on the glossy original ground of silk. Other effects are given by a paste prepared from 200 parts of smalt, 775 parts of aqueous (1:1) British gum (dextrin) and 25 parts of mono- or dimethylolurea. By printing a fabric with this paste and then treating with steam, dark-blue prints, fast to rubbing and washing, are obtained.

Heynert and Lucius<sup>16</sup> used a composition consisting of 15-60 per cent of cellulose esters or ethers together with 85-40 per cent of a syrupy condensation product from urea or thiourea and formaldehyde for the ornamentation of fabrics and yarns. Paper, linen or other cellulosic material which is to receive color or design may be impregnated with urea resins and then hot-pressed.<sup>17</sup>

Acid dyes, e.g., a dye obtained from 5-aminotoluene-2-sulphonic acid and  $\beta$ -naphthol, are converted into lakes in the presence of aqueous solutions of urea-formaldehyde resins.<sup>18</sup> Urea resins dissolved in chlorohydrins are used in conjunction with the usual printing media to render pigments and dyestuffs, applied to fabrics, fast to washing.<sup>19</sup> The affinity of textiles for dyes may be varied by a previous impregnation or printing with an aqueous solution of a urea-formaldehyde condensation product.<sup>20</sup> The condensate is rendered insoluble prior to the dyeing process.

### IMPREGNATION OF PAPER AND CELLULOSIC MATERIALS WITH UREA RESINS

Mention has already been made of the treatment of paper with a urea condensate. According to Atsuki and Matsuoka,<sup>21</sup> urea resins in general increase the dielectric strength of paper when used as an impregnant, although spruce sulphite paper impregnated with a urea resin exhibits a lower mechanical strength than the untreated substance. Paper resembling "glassine" is obtained by adding a gel prepared by treating a 2 per cent urea solution with formaldehyde and acetic acid to the pulp contained in the beater.<sup>22</sup>

Lionne<sup>23</sup> modified the impregnation method by first preparing a gum-like material through the interaction of 100 parts of urea, 50 parts of acetaldehyde, 50 parts of glycerol (plasticizer) and 10 parts of glacial acetic acid. The reaction is carried out in the cold, and 100 parts of the stock so obtained are treated with 150 parts of formaldehyde and 2-5 parts of ammonium sulphate. The resultant jelly, if allowed to stand, would change gradually into a hard resin, unsuited for incorporation with paper. Consequently, a "retarder" is introduced prior to the jelly-formation in order to reduce the tendency of the jelly to pass into the higher condensation stages. Lionne states that a mixture containing 100 parts of water and 2.5 parts of Karaya gum accomplishes this aim. In preparing the paper, the weight of jelly taken varies from 5-100 per cent of the weight of pulp, and the dispersion of the components is carried out in a beater. The paper is finally calendered (usually with heat) and then appears translucent and seemingly parchmentized. Simultaneously, the tensile strength and the chemical and electrical resistance are said to be improved. If the paper is hot-calendered, the resin is converted into its insoluble stage, reducing the flexibility of the product.

Urea resins are utilized as a means of insuring the permanence of designs or decorations on paper and fabrics. The paper is dipped in the resin (urea- or thiourea-formaldehyde) solution; and, on the application of heat and pressure (by passing through heated rollers), a smooth lustrous surface is obtained which can be washed without marring the surface.<sup>24</sup> The incorporation of finely comminuted fibers has been suggested as a means of preventing the formation of

fine cracks within the surface.<sup>28</sup> In experiments carried out by Ellis<sup>29</sup> on the production of laminated paper with differently colored strata, a mixture of 1 part of acetone-formaldehyde resin with 3-4 parts of urea-formaldehyde resin is employed as an impregnant. A vari-colored effect is obtained by dyeing the paper with different colors or by treating the resin solutions with various pigments. A highly calendered, waterproof sulphite cellulose paper coated on both sides with a condensate formed from urea and formaldehyde and then hardened was used by Wickel<sup>30</sup> in the manufacture of drinking-straws. An additional method for the manufacture of transparent paper employs parchment paper which is treated with a urea-formaldehyde condensation product, dried, and heated to 120-150°C. to make it transparent.<sup>31</sup> Paper or other absorbent medium, impregnated with a resin from formaldehyde or furfural with phenol, cresol or urea, was used in the

Courtesy Plaskon Co.

FIG. 107.—A Scale Made of a Urea-Formaldehyde Resin.

construction of acoustic diaphragms.<sup>32</sup> Porous panels of cellulosic fibers can be impregnated with an alcoholic solution of a urea-formaldehyde condensation product which is later made insoluble by heating at 100°C.<sup>33</sup> Boards for building or fitting purposes can be formed by drying (with heat and pressure) sheets obtained from aqueous suspensions of wood fiber containing, in solution, urea, thiourea and an aldehyde.<sup>34</sup> A sound-record blank consists of a core of paper impregnated with urea resin and coated first with a nitrocellulose solution and then with one of cellulose acetate.<sup>35</sup>

Urea resins are produced as covering layers on various materials (e.g., asbestos plates, absorbent paper or printed material) by impregnating with a suspension

of the condensate, drying and hardening with heat and pressure.<sup>32</sup> The suspension consists not only of urea-formaldehyde condensate suspended in water or an organic solvent but also the solid resin swollen by the liquid phase. Fillers, pigments and plasticizers together with bronze powder or metal filings may be incorporated with the solid resin. Lahousse<sup>33</sup> prepared impregnated paper for the manufacture of electric condensers by using amido substances (including anilides, thioamides, urea, ureines, ureides, thiourea and sulphonamides) with resins, waxes and paraffin.

Combustible materials can be fireproofed by treatment with solutions or suspensions of fireproofing salts in urea-formaldehyde condensation products to which have been added pigments for the production of decorative effects.<sup>34</sup>

### NON-SHATTERING GLASS AND ADHESIVES

The quality of light-fastness which urea resins possess to a high degree has caused them to be suggested as adhesives in the production of safety glass.<sup>35</sup>

Davis<sup>36</sup> prepared a resin solution for use as an interlayer and adhesive in safety glass by first evaporating 10 parts of dicyanodiamide, 28 parts of thiourea, 22 parts of urea, 126 parts of 40 per cent formaldehyde and 1.4 parts of formic acid at 70°C. until the mixture corresponded to 134 parts by weight. Then, 10 parts of the prepared composition are shaken with 50 parts of acetone, and to 37 parts of the clear extract are added 6.1 parts of low-viscosity nitrocellulose dissolved in a mixed solvent containing 16.5 parts of acetone, 12 parts of alcohol, 18 parts of benzene, 1.8 parts of benzyl alcohol, 9 parts of mono-ethyl ether of ethylene glycol and 5 parts of butyl phthalate. The adhesive solution is painted or otherwise spread on one side of each of the glass sheets to be used and is allowed to dry for 2-10 minutes. A cellulose acetate sheet is applied as an interlayer between two such coated glass sheets, and the whole is subjected to a pressure of 500 lb. per square inch, heat being applied until the temperature reaches about 50°C.

This procedure with a number of modifications is the basis for several proposed methods of making nonshatterable glass. Various cellulose esters, ethers, plasticizers and dyes may be added,<sup>37</sup> and the hardening of the resin layer may be hastened by the addition of a hardening catalyst.<sup>38</sup> Voluinkin<sup>39</sup> used alcohol as the solvent for the urea resin, the alcohol being removed before pressing by drying at a temperature of about 100°C. Segond<sup>40</sup> prepared a product suggested for use in safety glass by condensing urea with formalin in the presence of a mixture containing dry zinc powder, sodium chloride, trioxymethylene and hexamethylenetetramine.

Ford and McCarroll<sup>41</sup> recommended uniting sheets of rough, translucent glass and interposed cellulosic sheets with compositions having the same refractive index as the glass. A composition achieving this result is composed of 50-55 per cent of cellulose nitrate, 20-25 per cent of urea-formaldehyde resin, 10-15 per cent of camphor and 10-15 per cent of tolyl phosphate. As an adhesive for the glass, Rossiter<sup>42</sup> used a mixture of about 30 per cent of urea resin and 70 per cent of gelatin. A dicyanodiamide-formaldehyde resin may be substituted for the urea resin, and the final adhesion after assembling the sheets is effected by compression at 80°C. These resins were

similarly used by Hamoir<sup>43</sup> for making safety glass. Uncoated glass sheets can be united with an interposed film of plastic material containing on its surface a compatible synthetic resin adhesive, according to Moss and Crutchfield.<sup>44</sup>

A cold adhesive is formed from the condensation products of urea, thiourea, aldehydes, water and, if necessary, catalysts increasing the consistency of the adhesive.<sup>45</sup> Taylor and Keller<sup>46</sup> found that by heating urea, thiourea or their derivatives at 90°C. with paraformaldehyde in the presence of water or steam, a thin paste formed which could be evaporated to a syrupy consistency and then used as an adhesive or size. Layers of material can be bonded by the use of condensation products derived from polymerized formaldehyde and urea. A heat-treatment at 150°C. for 30 seconds effects the final hardening.<sup>47</sup> An adhesive containing nitrocellulose, a softening agent, a solvent and a urea-aldehyde condensation product

was prepared by Benteli.<sup>48</sup> Fuwa<sup>49</sup> employed a urea resin mixed with water glass and borax as an adhesive coating for the surface of ultraviolet-ray reflectors.

A network of organic fibers, such as wool or yarn, carrying a transparent or translucent synthetic resin prepared from urea and formaldehyde has been employed for cold frames used in horticulture.<sup>50</sup> An adhesive prepared from a urea resin and albumin can be used in making cellulose foils consisting of two layers of cellulose only one of which is capable of absorbing water.<sup>51</sup>

Browne and Hrubesky<sup>52</sup> found that by adding urea-formaldehyde condensation products to animal glues it was possible to render glued joints more water-re-

sistant. A glue mixture containing urea-formaldehyde compositions gels like an untreated glue sol when it is chilled to room temperature while fluid. If the chilled jelly is kept at room temperature for a period longer than its working life, it cannot be melted again even on heating in a water-bath.

Baldwin<sup>66</sup> used a cement containing urea-formaldehyde resins in the production of linoleum and other floor coverings. A thin sheet material, e.g., paper, is placed on a supporting linoleum or felt base with an intervening cementing material containing a resin, a plasticizer and a modifier. Such a binder contains 50 parts of urea-formaldehyde resin, 25 parts of cumarone resin, 25 parts of rosin, 20 parts of tricresyl phosphate and 20 parts of dibutyl phthalate.

A resin developed by Eisenmann, Scholz and Wolf<sup>67</sup> for the production of abrasive paper is made by reacting hydroxyl-bearing esters of a fatty acid containing at least 10 carbon atoms with dimethylolurea in acid solution.

A method given by these investigators involves the preparation of an ester from one mol each of glycerol and linseed fatty acids. Then 250 parts of the ester are dissolved in 300 parts butyl alcohol and 50 parts ethyl alcohol; 13 parts of a 5 per cent solution (in ethyl alcohol) of urea nitrate are added, then 250 parts dimethylolurea. The batch is heated to 90°C. giving a solution of a resin. Later, 20 parts of tertiary sodium phosphate are added to neutralize. After settling, the phosphate is filtered off. A yellow-brown resin is obtained on evaporation of the solvent. Abrasive paper is made by applying to paper a 40 per cent toluol solution of the resin and distributing carborundum grains over the surface. The resinous adhesive is hardened by heating.

#### UREA RESINS USED WITH RUBBER

A composition of alkyd resins with urea-formaldehyde condensation products and emulsified rubber or rubber substitutes was found by Baird and Bunbury<sup>68</sup> to give flexible, semi-glossy coatings with good weathering qualities.

An alkyd-urea-formaldehyde resin is first made by heating 10 parts of alkyd resin, 20 parts of glycol monoethyl ether and 10 parts of dimethylolurea for about 30 minutes. The alkyd resin employed is prepared by heating 148 parts of phthalic anhydride, 62 parts of glycerol and 150 parts of castor oil at 190-200°C. for 3-4 hours while a current of carbon dioxide or nitrogen is passed through the reaction mixture. The coating is made by dissolving 30 parts of alkyd resin and 11 parts of the alkyd-urea-formaldehyde resin in 14 parts of solvent naphtha, 45 parts of butyl alcohol, 65 parts of water and 10 parts of rubber substitute emulsion and passing the stirred mixture through a colloid mill. The product can be applied by coating, dipping, spreading or spraying and is dried at temperatures above 90°C.

Uncured rubber cloth can be coated with a lacquer consisting of a polyhydric alcohol-polybasic acid resin, a hydroxylated fatty oil and a urea-formaldehyde condensation product.<sup>69</sup> The coating is hardened and the rubber is simultaneously vulcanized by treatment with a solution of sulphur chloride in carbon disulphide. Urea-aldehyde resins modified with phenols may be used, according to Thompson,<sup>70</sup> as adhesives for the attachment of rubber to metal, porcelain, glass or wood. The reaction product of thiourea and an aldehyde-ammonia serves, in small proportions, as an accelerator for the vulcanization of rubber.<sup>71</sup> Another group of accelerators

is produced by mixing mercaptans or mercapto compounds with organic bases including thiourea and guanilyureas.<sup>66</sup>

By condensing urea with not more than 1 mol of formaldehyde in ammoniacal solution, Spiecker<sup>67</sup> obtained a preservative for latex. The material formed is soluble in water and remains liquid when concentrated as far as possible under reduced pressure. It is slowly decomposed on standing, evolving ammonia.

A resin formed from phenol glycerol ether, urea and formaldehyde increases the resistance of rubber masses to chemical and electrical influences.<sup>68</sup> By dispersing rubber in a liquid urea-formaldehyde resin, a plastic composition is obtained.<sup>61</sup>

### MISCELLANEOUS USES OF UREA RESINS

Rochet<sup>69</sup> reported the preparation of artificial silk directly from the condensation products of urea and formaldehyde.

As an example, 30 kg. of urea are dissolved in 80 l of commercial formalin, and the resulting solution is treated with calcium carbonate and filtered. The filtrate is refluxed for 3-4 hours in an apparatus fitted with a condenser. The condenser is then removed and the solution is further boiled until a test-sample gives a precipitate when poured into water. At this moment, 3 l. of a saturated solution of disodium hydrogen phosphate are added and the product is evaporated under reduced pressure until half of the water initially contained is removed. After cooling, the product is spun, using as a coagulating bath a saturated solution of magnesium sulphate (or sodium sulphate) to which sulphuric acid has been added until the solution turns bromophenol from blue to yellow. Cyanamide or dicyanodiamide can be used to replace the urea. Urea resins were incorporated by Dreyfus<sup>64</sup> in cellulose esters or ethers for the manufacture of silk films and threads.

The water-soluble types of urea resins are used in conjunction with deodorizing and preserving agents for the preservation of perishable animal products such as hides.<sup>64</sup> Taylor and Keller<sup>70</sup> employed a transparent, syrupy urea-aldehyde condensation product for the impregnation of leather. The treated material was dried, mixed with pigments and finally molded. Tanned leather was given an after-treatment with an aqueous solution of a urea-aldehyde condensate by Bergmann<sup>71</sup> in order to fix the residual tanning substances. Brunner and Scheele<sup>72</sup> applied urea-aldehyde resins to the preserving of physiological specimens (e.g., insects, plants, reptiles and fishes). The specimen is covered with a free-flowing resin and air is drawn from the interior of the specimen by evacuating. Finally, the liquid condensation product is converted into an insoluble solid by heating, and the transparent mass is polished. Urea and other fertilizers which are hygroscopic or have a tendency to cake during storage can be preserved by coating with a urea-formaldehyde condensate.<sup>68</sup>

Prüfer and Dulik<sup>66</sup> extended the use of urea resins to the production of light-sensitive layers for photographic purposes. Thus, 20 cc. of a solution of a urea-aldehyde condensation product that is soluble in warm water and contains the equivalent of 20-30 per cent of solid urea are heated and emulsified with silver halide. The product is cooled, washed and finally applied while warm to glass, film or paper. If a copy is to be made on a plate of zinc or copper, the metal is first thoroughly cleaned and then is covered with a chromated resin solution which is composed of 10 cc. of a urea resin containing 12-15 per cent of solid urea and diluted with 5-10 cc. of water, 2 cc. of a 10-20 per cent solution of ammonium dichromate, 2 drops of a 5 per cent albumin solution and 2 drops of a 10 per cent solution of copper bromide (acting as an accelerator). The plate is next dried in a centrifuge. A copy is made from a ruled negative in daylight or with artificial light and is developed for a few seconds under a water-jet. After the copy has been colored with an aqueous solution of a dyestuff and subsequently dried, the etching can be effected without a previous treatment with heat.

Ink for use in intaglio printing can be prepared by incorporating finely divided or dissolved coloring matter with a urea resin dissolved in a volatile, organic

solvent.<sup>70</sup> The solvents employed are alcohols (with less than 6 carbon atoms in the molecule), ketones and esters or hydrocarbons of the aromatic series. Thus, lampblack and the calcium salt of an azo dyestuff prepared from aniline and 2,6-naphtholsulphonic acid are triturated with a urea-formaldehyde condensation product dissolved in a mixture of isobutanol and ethanol. Laking of dyes with urea resins has been mentioned previously. Water-soluble urea-formaldehyde resins were used by Reindel and Ohmer<sup>71</sup> in the preparation of color lakes from acid dyes.

Films may be manufactured from urea-aldehyde resins by applying viscous solutions of the latter, preheated to 100°C., to a travelling base and allowing them to solidify.<sup>72</sup> This solidification is effected at temperatures of 70-100°C.,

<sup>72</sup> R. Weingand, British P. 318,580, 1928, to Wolff & Co.; *Chem. Abs.*, 1930, 24, 2256. British P. 298,631, 1927; *Chem. Abs.*, 1929, 23, 2990. French P. 661,598, 1928; *Chem. Abs.*, 1930, 24, 476.

the films being removed when no longer sticky on the surface. Softening agents (glycerol or methylcyclohexyl adipate) should be added to the resin.

Various other applications of urea resins have been suggested. Goldscheider and Tuschinsky<sup>73</sup> prepared imitation frosted or stained glass by impregnating wire gauze or a fabric with a urea-formaldehyde-resin lacquer and applying granulated glass to the surface. Fibrous materials, soaked with urea- or thiourea-formaldehyde condensation products and then hot-molded with small quantities of an acid condensing agent, were proposed as brake linings.<sup>74</sup> As referred to in the section on the impregnation of paper, acoustic diaphragms for use in telephone transmitters can be manufactured from urea condensation products.<sup>75</sup> Rickets<sup>76</sup> prepared such diaphragms by treating paper, linen, silk, artificial silk or mercerized cotton with a urea or thiourea resin. Artificial cork masses can be manufactured by impregnating cork meal with less than 30 per cent of its weight of unhardened urea resin together with a softening or plasticizing agent (e.g., glycerol) and compressing the resultant composition.<sup>77</sup> Aqueous solutions of urea resins mixed with acids and acid salts are employed in the treatment of wood.<sup>78</sup> A layer of urea resin with added pigments has been used as a coating for ebonite panels to prevent deterioration by light.<sup>79</sup>

A product obtained by condensing urea with hexamethylenetetramine was used by Mossgraber<sup>80</sup> as a protective colloid for dispersions of metals or metalloids in organic liquids such as glycol, glycerol, hydrocarbons and animal or vegetable oils. The oily substance obtained by the prolonged refluxing of formaldehyde solution with di-o-tolylthiourea was employed by Schmidt<sup>81</sup> as an inhibitor for sulphuric acid pickling baths. Schlacht<sup>82</sup> applied coatings of urea resins as a preservative for soil profiles. A sheet of celluloid is coated with a solution of the colorless, water-soluble urea resin and is pressed against a vertical, smoothly-faced profile wall. After 5-10 minutes, the sheet is peeled off with a thin layer of soil adhering. When this sheet is dried, a permanent "monolith" of the profile is obtained.

## Chapter 31

### Thiourea Resins. Mixed Urea-Thiourea Resins

Thiourea, because of the water-resistance that it imparted, was heralded as an all-important constituent of molding compositions,<sup>1</sup> but it has proved somewhat intractable from the standpoint of the molder. Ordinary molds (see Chapter 28) are stained by thiourea-containing powders, necessitating the use of stainless steel or chromium plated molds. Thus, the molder was unable to employ his usual equipment and faced the necessity of purchasing new and more expensive molds. Another feature handicapping the development of thiourea-formaldehyde moldings is their characteristic slow rate of cure. Thiourea resins require a curing time of about ten minutes, comparing very unfavorably with the rapidity with which Bakelite resins cure. As the molding industry has developed largely along the lines of piece work, the time involved in individual operations seriously affects the cost of the final product and the profit derived therefrom. Since urea resins cure much faster than thiourea products, the expedient of preparing a resin containing both urea and thiourea was tried. The composite resin cured more expeditiously and was resistant to water, but still exerted a deleterious action on the mold. In modern practice, water-resistant ware can be fabricated from urea resins alone, and hence thiourea-formaldehyde condensates are no longer manufactured extensively.

#### PRODUCTION OF THIOUREA AND RELATED COMPOUNDS

Thiourea, as synthesized by Claus<sup>2</sup> in 1873, was a colorless crystalline compound melting at 172°C. It dissolved in water, was slightly soluble in alcohol and difficultly soluble in ether. Inghilleri<sup>3</sup> described the synthesis of thiourea and ammonium thiocyanate by heating carbon disulphide and ammonium carbonate. Ammonium dithiocarbamate is first formed and is converted successively into ammonium thiocyanate and thiourea by further heating.

The conversion of ammonium thiocyanate to thiourea (analogous to Wöhler's synthesis of urea) is conducted extensively on a commercial scale, since the wet process for the purification of illuminating gas offers a readily available supply of the thiocyanate.<sup>4</sup> A 35 per cent solution of ammonium thiocyanate obtained as a by-product in the gas industry is crystallized by concentration in a resistant vessel made of a non-ferrous metal. The crystals are then heated for several hours at 140-160°C. under atmospheric or reduced pressure. A 25 per cent yield of thiourea is obtained and separated from the unchanged thiocyanate which is further treated with heat. Donauer prepared thiourea by heating ammonium

<sup>1</sup> See a review by K. M. Chance, *Australian Plastics and Allied Trades Rev.*, 1933, 2 (2), 13; *Chem. Abs.*, 1934, 28, 533. Although resins made from urea and thiourea represent a type of amino linkage forming aminoplasts of a similar character generically considered (see Chapter 28), it should be noted that despite their general equivalency thiourea possesses certain disadvantages which render it less useful than urea for various molding purposes.

<sup>2</sup> Claus, *Ber.*, 1873, 6, 727. The melting point of thiourea is now considered to be 182°C. See, for example, "International Critical Tables," McGraw-Hill Book Co., N. Y., 1928, I, 177.

<sup>3</sup> G. Inghilleri, *Gazz. chim. ital.*, 1909, 39 (1), 634; *Chem. Abs.*, 1911, 5, 696.

<sup>4</sup> *British Plastics*, 1934, 5, 550.

thiocyanate *in vacuo* at 160°C., then allowing the material to cool slowly to 110-120°C. when it was granulated.<sup>4</sup> The cooled product was added to sufficient water at 10-14°C. to maintain the unchanged ammonium thiocyanate in solution at -10°C. The undissolved material was then crystallized from hot water, yielding thiourea. A large proportion of the thiourea industrially produced is prepared from crude calcium cyanamide (see Fig. 110). If this compound is dissolved in water at a temperature low enough to prevent the substantial decomposition of the cyanamide

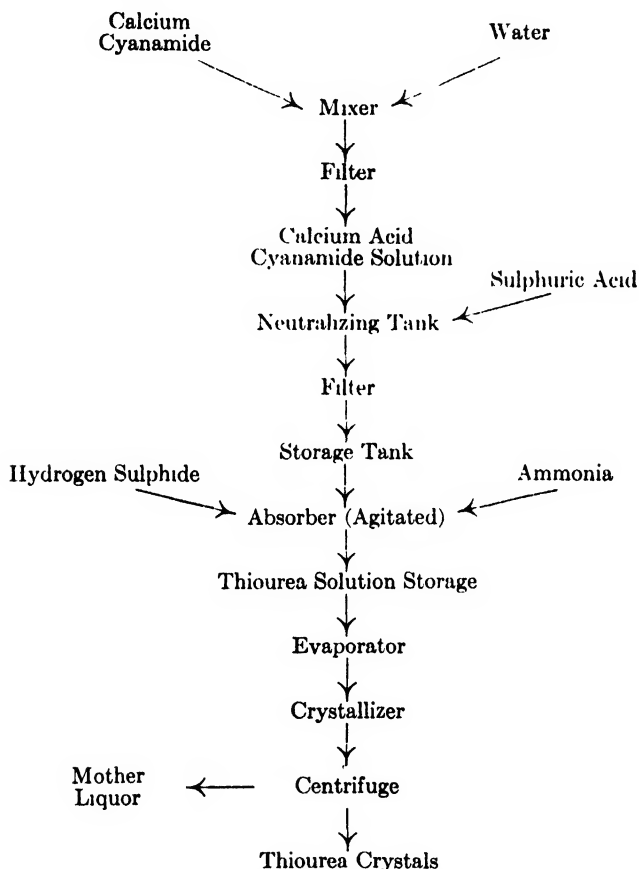

FIG. 110.—Flow Diagram for the Preparation of Thiourea from Calcium Cyanamide.  
(R. V. Heuser.)

present, filtered and treated with a solution containing sulphur and ammonium sulphide, thiourea is formed.<sup>4a</sup> A process described by Heuser<sup>5</sup> utilized hydrogen sulphide and ammonia in conjunction with the cyanamide solution to form thiourea. Mayen and Wolfes<sup>6</sup> prepared an aqueous cyanamide solution, first, by extracting

<sup>6</sup> H. Mayen and O. Wolfes, German P. 452,025, 1924, to E. Merck; *Brit. Chem. Abs.* B, 1930, 315. See also W. Schulenburg, U. S. P. 1,977,210, Oct. 16, 1934; *Chem. Abs.*, 1935, 29, 181.

calcium cyanamide at 15°C. and precipitating the calcium with carbon dioxide. The filtered solution is then saturated (at 15-60°C.) with hydrogen sulphide in the presence of water-soluble bases (ammonia). After concentration, the thiourea is deposited in the form of crystals. In another preparative method,<sup>7</sup> calcium sulphide is added to an aqueous solution of calcium cyanamide, and carbon dioxide is led in at a pressure of 5 atmospheres and a temperature of 75°C. The nascent hydrogen sulphide produced reacts with the cyanamide to form thiourea. A similar procedure<sup>8</sup> entails adding calcium cyanamide and calcium sulphide (in the theoretical proportions) to 5 times their weight of water, treating with carbon dioxide to precipitate all the calcium and then heating at 75°C. for 1-1.5 hours with stirring. The thiourea is recovered by filtration and evaporation.

Flemming and Klein<sup>9</sup> described the preparation of thioureas from mustard oils and diarylguanidines, in inert solvents at temperatures below the decomposition points of the products. The method is more applicable to complex, substituted types. Thus, N,N'-di-o-tolyl-N''-phenylthiocarbamidoguanidine (m. p. 179-180°C.) was obtained in 93 per cent yield from di-o-tolyl-guanidine and phenyl mustard oil in boiling benzene. Diarylthioureas are formed by treating carbon disulphide with an excess of an amine, without using neutral solvents or water.<sup>10</sup> Aniline, e.g., gives thiocarbanilide with carbon disulphide.

The vapor-phase reactions of carbon disulphide and aniline were employed by O'Brien<sup>11</sup> in the production of thioureas. Carbon disulphide vapor is introduced at the bottom and aniline at the top of a tower divided into a number of compartments, connected by pipes arranged to insure an intimate mixing of the reactants. The temperature of the tower is maintained at about 130°C. by electric heating coils or superheated steam. Hydrogen sulphide escapes through the top of the tower, and the reaction product (diphenylthiourea) flows down into a trap containing benzene, from which it is separated and dried. A catalytic carbon disulphide-amine process for thiourea was developed by Hand and Roberts.<sup>12</sup> Aromatic amines are heated at 46°C. with 60 per cent of carbon disulphide in the presence of an alkaline catalyst volatile below 75°C. (0.1-0.25 per cent of concentrated ammonia solution). The evolved hydrogen sulphide vapors are scrubbed by passing through a tank containing a second charge of amine and catalyst, this charge being admitted to the mixer when the reaction is complete in the first charge and the excess of carbon disulphide and catalyst have been recovered by distillation at 75°C. Bedford and Sibley<sup>13</sup> employed a p-nitroso compound (p-nitrosophenol or p-nitrosodimethylaniline) to remove the hydrogen sulphide formed in the condensation of aniline and carbon disulphide. The hydrogen sulphide combines with the nitroso compound, aniline and carbon disulphide to form a derivative of thiocarbanilide. This removal of hydrogen sulphide accelerates the production of thiocarbanilide. The mechanism of the carbon disulphide-aniline reaction was studied by Snedker<sup>14</sup> who postulated the following reactions:

Uedinov, Drozdov and Stepanov,<sup>15</sup> in a study of the same reaction, found that a maximum yield of thiocarbaniide was obtained with a 10-20 per cent excess of carbon disulphide, but an excess of aniline greatly reduced the yield owing to a tendency to form triphenylguanidine. Diphenylguanidine is made by treating aniline with cyanogen chloride, distilling the excess aniline and adding a weak alkali.<sup>16</sup> The reaction of a mercaptan and a cyanamide in aqueous or alcoholic solution yields isothiourea ethers.<sup>17</sup> The mercaptan is passed in vapor form through the solution. S-Ethyl-isothiourea is thus obtained from ethylmercaptan and cyanamide. In a spectroscopic study of thiourea, Rivier and Borel<sup>18</sup> concluded that thiourea and trimethylthiourea can exist only in the *iso* state and do contain the C=S group. Thiourea derivatives<sup>19</sup> may be prepared by heating the mineral acid salts of amines such as aniline hydrochloride, p-phenetidine hydrochloride and 4-amino-indazole hydrochloride with an alkali thiocyanate in the presence of an inert organic solvent.

### THIOUREA RESINS

The conditions under which urea or thiourea will form resins with formaldehyde which can be used in molding are limited and must be carefully controlled. According to Novotny and Wilson,<sup>20</sup> the condensation markedly tends to form a gel, from which the mother liquor may be removed only with difficulty. Catalysts increase this tendency, and even when the water is removed, the resin is liable to be almost infusible and of little use for molding. As a result, many of these products, as described later, are cast rather than molded.

Novotny and Wilson developed a method of removing water from the liquid condensate without promoting gel formation. The reaction between thiourea and formaldehyde is carried out in a slightly alkaline medium without heating. Specifically, 1 part of barium hydroxide is dissolved in 160 parts of 36 per cent formalin and 120 parts of thiourea are added with stirring. The temperature of the mixture is held below 40°C. and the reaction is complete in 2 hours. To counteract the slight acidity that may develop, 2 parts of ammonium hydroxide (sp. gr. 0.9) are added, giving a stable solution that may be kept for long periods. Carbon dioxide is led into the mixture to precipitate barium carbonate. The clear solution, prior to its evaporation, serves as a varnish and an impregnant (e.g., in the preparation of laminated materials). Water may be removed from the aqueous condensate by freezing or by evaporation, giving an almost colorless, brittle product. The freezing treatment

yields a mixture of ice and resin which is then finely divided in an impact pulverizer and carried through currents of air (air flotation) until the ice melts, separating from the resin particles. The resin is recovered in a cyclone separator as a fine powder. One advantage of this method is the possibility of control of the condensation which may be stopped at any point by subjection to the freezing process. The non-gelling character of the solution permits recovery of the resin by spraying the liquid through nozzles into a heated room or into a heated cyclone separator.

A relatively early description of the use of thiourea in conjunction with formaldehyde for resin formation is contained in the work of John,<sup>21</sup> who heated 1 part of urea or thiourea with 5 parts of commercial formalin until a part of the water had distilled and a glue-like mass remained. Prolonged heating gave a glassy, insoluble material.

A solution of a thiourea-formaldehyde resin capable of heat-hardening and applicable as a varnish was produced by Schmidt<sup>22</sup> by carrying out the condensation in an appropriate solvent. Thus, 100 parts of thiourea (part of which may be replaced by urea) are dissolved in 100 parts of ethyl lactate and a like amount of the mono-ethyl ether of ethylene glycol. Then 60 parts, by weight, of paraform are added, and the mixture is refluxed for 2-3 hours and filtered. The resulting solution can be used directly as a varnish, as a lacquer (with thinners) or as a component of molding mixtures.

The condensation is not necessarily carried out in a solvent. An aqueous solution of formaldehyde (e.g., 650 g. of a 40 per cent solution) may be refluxed with thiourea (300 g.) for 1.5 hours.<sup>23</sup> The addition of 1000-1500 cc. of water precipitates the resin, which is fusible at 100°C. and soluble in the organic resin solvents. This non-reactive resin is dissolved in a solvent, capable of dissolving paraformaldehyde, for further treatment. Paraform (50-75 parts) is added to the solution which is then useful as a varnish or impregnant. The films prepared by hardening this resin are resistant to alcohol, acetone and benzene. The almost universal presence of formic acid in commercial formaldehyde which often gives the thiourea-formaldehyde resins an undesirable acid reaction caused Rossiter<sup>24</sup> to attempt to remove it without the use of alkali by passing a stream of dry air or an inert gas through the liquid condensate during evaporation below 100°C. As with resins from urea itself, if thiourea and aqueous formaldehyde are condensed, the first product is water-soluble and may be concentrated to a syrup.<sup>25</sup> This syrup is converted into a moldable material by adding a filler and an acid substance. The dried product, containing the condensate, wood flour and oxalic acid, sodium hydrogen sulphate, potassium tetroxalate or aniline hydrochloride as hardening substances, is hot-molded.

A mixture of thiourea and urea may be employed to replace thiourea, or the two substances can be condensed separately with formaldehyde, and the water-soluble, initial condensates mixed in solution.<sup>26</sup> The mixture is concentrated by evaporation. As noted earlier in the chapter, slow curing is a disadvantage of thiourea resins; however, the combined urea-thiourea-formaldehyde resin cures more rapidly and yet retains the solubility of the purely thiourea-formaldehyde combinations. If 25 per cent or less of the thiourea is replaced by urea, clear

resin syrups are formed, but above this figure turbid products, which still cure rapidly, result. The turbidity is obviated by the incorporation of a small amount of ammonia. Traces of acid or alkali do not affect the solubility of thiourea resins. In an example illustrating the preparation of mixed resins, 95 lb. of thiourea and 74 lb. of urea are dissolved in 371 lb. of formalin containing 120 lb. of formaldehyde. The mixture is warmed to 50-70°C. until all the thiourea and urea have

dissolved. The turbid solution obtained after standing a few hours to effect condensation is evaporated at 70-80°C. by blowing a brisk current of air through it until the required consistency is reached.

From 2 to 10 per cent of free thiourea has been added to function as an accelerator in urea-aldehyde reaction products which are being ground in preparation for molding.<sup>27</sup>

Gams and Widmer<sup>28</sup> also described a method of resin formation based on the use of urea and thiourea. The formaldehyde is first condensed with not more than 1 mol of urea (per mol of aqueous formaldehyde) at a temperature of 100°C. until a sample

<sup>27</sup> E. C. Rossiter, British P. 351,094, 1930, to Brit. Cyanides Co.; *Chem. Abs.*, 1932, 26, 5392.

<sup>28</sup> A. Gams and G. Widmer, U. S. P. 1,854,896, Apr. 19, 1932, to Soc. anon. pour l'ind. chim. à Bâle; *Chem. Abs.*, 1932, 26, 2392. British P. 275,995, 1927; *Brit. Chem. Abs. B*, 1927, 219.

of the reaction mixture yields a precipitate on dilution with water. Thiourea is then added to bring the total amount of urea and thiourea to 1 mol for each 1.6 mols of formaldehyde, and the solution is evaporated and hardened. These proportions enable clear, glassy resins to be prepared from a minimum amount of formaldehyde. With urea and formaldehyde alone, a departure from the ratio of 2 mols of formaldehyde per mol of urea gives non-glassy or even milky films. Restriction of the amount of formaldehyde by using a urea-thiourea combination frees the final products from objectionable aldehyde odors. A small amount (less than 1 per cent) of ammonium sulphate or ammonium thiocyanate added with the thiourea serves as a catalyst in hardening the resin. At the time of adding the thiourea, a considerable amount of free aldehyde is present in the solution. The fixation of the formaldehyde is normally accelerated by heating, but if the solution is made neutral or feebly alkaline, a slow reduction of the quantity present ensues on standing.<sup>20</sup> By this treatment, the resins give water-resistant varnishes. Thus, 120 parts of urea are dissolved in 334 parts of 36 per cent formaldehyde, mixed with 30 parts of blood charcoal and filtered. The clear solution is heated for 6 hours at 98°C. in an autoclave equipped with a stirring device. After neutralizing the product to litmus with a dilute sodium hydroxide solution, 45 parts of thiourea are added. On standing for 2 days at room temperature, the free formaldehyde is reduced from 6 per cent to 0.5 per cent by volume, and the viscosity of the solution remains unchanged.

Kraus<sup>20</sup> described the preparation of resins, that can be molded under heat and pressure, by boiling urea, thiourea and urethan with aqueous formaldehyde in the presence of an acid catalyst (acetic acid) until a hydrophobe product separated on cooling. The products of the reaction are rapid-hardening, water-stable resins.

An additional method<sup>21</sup> of preparing urea-thiourea resins includes the use of a mixture of 1 mol of urea and 1 mol of thiourea pretreated in non-acid solution with 2 mols of formaldehyde. This is then gradually added to a hot solution of 1 mol of urea and less than 2 mols of formaldehyde containing an acid condensing agent. The final molar ratio should be 1 mol of total urea and thiourea to 1.4-1.8 mols of formaldehyde. Specifically, 300 parts of urea are dissolved in 1500 parts of previously neutralized, 30 per cent formaldehyde, and 5 parts of 10 per cent acetic acid are added. After heating to the boiling point, a solution of 562 parts of thiourea and 450 parts of urea in 1500 parts of neutral formalin is introduced during a period of 15-30 minutes, and the boiling is continued for 45-60 minutes. At the end of this time, there are formed hydrophobe masses which precipitate on cooling. The precipitated condensate is mixed with cellulose, dried at a low temperature, ground and hot-molded.

A two-stage reaction of thiourea and urea with formaldehyde was carried out by Smidth.<sup>22</sup> First, 225 grams of urea are dissolved at a temperature of 25-50°C. in 640 cc. of a slightly acid, 35 per cent formaldehyde solution. This mixture is then vacuum distilled below 100°C. to remove most of the water. Next, 63 g. of thiourea are added and a second vacuum distillation is performed at 150°C. until nearly all of the water is removed and the product is as viscous as possible (but still can be cast). The resin, cast under pressure, is hard and brittle, but comparatively soluble. It is finally heat-treated at 95°C. for three days and is transformed into a transparent, tough, insoluble and infusible product. Before final hardening, the cast resin may be ground, mixed with fillers and modifiers and molded.

A variation of this method, designed to improve the water-resistance of the

<sup>20</sup> A. Gams, G. Widmer and K. Frey, U. S. P. 1,890,033, Dec. 6, 1932, to Soc. anon. pour l'ind. chim. à Bâle; *Chem. Abs.*, 1933, 27, 1724. British P. 313,615, 1929; *Brit. Chem. Abs. resins, entails the condensation of 2 mols of slightly acid, aqueous formaldehyde with 1 mol of urea and, after a few minutes, the addition of 0.2 mol of thiourea.<sup>33</sup> When almost all of the water has been removed by vacuum distillation, formic acid is added, and the mixture is cast in molds and subsequently dried in an oven. Kelley and Deisley<sup>34</sup> developed a further modification of the preparation of urea-thiourea-formaldehyde condensation products. A mixture with a  $p_H$  of 5.2-7.0, containing urea, formaldehyde and ammonia solution, is first heated under reflux for a short time. Thiourea is then added, and refluxing is continued until a test sample no longer dissolves in water. The next step is the addition of a salt of a strong base and a weak acid (sodium acetate) in order to retard the gelation of the homogeneous, liquid condensate. By vacuum evaporation, 20 per cent of the water is removed, and the excess formaldehyde is converted by adding urea. As soon as 30 per cent of the aldehyde has reacted with urea, formic acid is introduced, and the concentration of the material is continued until the substance can be cast while hot in a mold. Other acids or acid salts (e.g., potassium phosphate or aluminum chloride) may replace formic acid in the final phase of the process. A molding composition suggested by Belfit<sup>35</sup> is prepared as follows. Urea and formaldehyde are condensed in solution at a  $p_H$  of 5.5 or higher at 110-120°C. under pressure. Then a minor percentage of thiourea is added to the solution, followed by a fibrous filler and a dye. The mixture is duly dried below 100°C and ground to 20- or 30-mesh.

Water-resisting resins were also produced by Rothera, Blythen and Gillespie<sup>36</sup> through heating a mixture of urea and thiourea (previously treated with alkaline formaldehyde solution) with acids. The heating is continued until the resin precipitates on cooling, and the products are further processed and hardened. Mains<sup>37</sup> used a 30-60 per cent solution of a urea-thiourea resin to impregnate wood for making trays and boxes. Fireproof paneling<sup>37</sup> may be made by impregnating asbestos and wood veneer with a heat hardenable urea-thiourea resin and pressing the sheets together. A method not necessitating the admixture of urea consists in the condensation of 1 mol of thiourea with 1.5 mols of aqueous formaldehyde at a  $p_H$  of 3.<sup>38</sup> The solution, to which volatile solvents are added, is used for the impregnation of fabrics and asbestos. The material obtained is dried at a low temperature and consolidated by hot-pressing, or is disintegrated to form molding and die-casting powders. Thiourea is added, in another method, in the final concentration of the syrup formed from 2 mols of formaldehyde and 1 of urea.<sup>39</sup> Sisley<sup>40</sup> prepared a mordant by condensing thiourea and an aliphatic aldehyde (formaldehyde, acetaldehyde or crotonaldehyde) in the presence of a mineral acid. The product may be used on wool, silk, leather or furs but not on cellulose acetate.

Eisenmann and Kuchenbuch<sup>41</sup> have also prepared thiourea-formaldehyde condensa-

tion products for use in resin formation. The condensation takes place in the presence of organic solvents (ethyl alcohol or acetone). As an example of the procedure,<sup>42</sup> 130 parts of trioxymethylene are dissolved in 320 parts of methyl alcohol and 18 parts of 50 per cent potassium hydroxide solution. Thiourea (152 parts) and an additional 18 parts of the potassium hydroxide solution are then added. After a short time, dimethylolthiourea, which can be solidified by washing with acetone, separates. A mixture of 136 parts of the dimethylolthiourea and 120 parts of dimethylolurea is suspended in 500 parts of methyl alcohol. While stirring, 5 parts of sodium tetroxalate are added, and the mixture is heated to gentle boiling for 1 hour. The clear, viscous solution is neutralized and filtered. This product, mixed with various other resins, cellulose esters or cellulose ethers, can be used in lacquer manufacture. By evaporating the solvent *in vacuo* from the solution, a viscous material, that forms a resin with good electrical properties after heat treatment, is obtained.

Ripper<sup>43</sup> produced molding compositions by condensing thiourea, or a mixture of thiourea and urea containing not less than 1 mol of the former per mol of urea, in boiling aqueous solution with formaldehyde. Not more than 3 mols of formaldehyde per mol of thiourea are used, or if the mixed ureas are employed, 2 mols of formaldehyde are added for each mol of urea and thiourea. Contact with cold water converts the resinous products to a fine powder that may be hot-pressed. Opaque final products are formed when the urea and thiourea are condensed simultaneously, whereas clear resins are given by initiating the reaction with thiourea before adding a solution of urea in formaldehyde.

In forming condensation products of urea, thiourea and formaldehyde, von Knilling<sup>44a</sup> proposed to carry out the reaction by fusion. In one example an intimate mixture of 200 parts of urea, 52 parts of thiourea, 240 parts of trioxymethylene, 6 parts of sodium acetate and 20 parts of formamide is heated at 140°C. for 20 minutes. A viscous melt is formed which on cooling becomes a hard white mass that may be powdered for use in moldings or adhesives.

Molding powders were made by Ripper<sup>44</sup> by heating aqueous formaldehyde with thiourea, alone, until a hydrophobe resin, which separated from a sample of the reaction mixture on cooling, had formed. On adding water, the condensation product was precipitated as a fine powder, which was separated, washed and dried. Bussard<sup>45</sup> also described the condensation of thiourea with aqueous formaldehyde, using an acid catalyst (e.g., acetic acid). Neuss<sup>46</sup> sought to improve the flow of the product obtained by the acid condensation of formaldehyde and urea without heat, by substituting thiourea for 10-20 per cent of the urea. Starch, in an amount equal to a multiple of the quantity of urea employed, is used as has been noted before as a filler in the condensation of urea or thiourea with formaldehyde.<sup>47</sup> Kappeler<sup>48</sup> described the preparation of a resin from thiourea and furfural. The thiourea is dissolved in dilute hydrochloric acid and furfural added. The mixture becomes warm and a hard black mass forms. The formation of resinous substances in the condensation of nitriles with thioamides was reported by Ishikawa.<sup>49</sup>

In an investigation of the reaction between aryl thioureas and both aliphatic and aromatic aldehydes, Schmidt<sup>50</sup> obtained several species of resins. Thus, di-*o*-tolyl-thiourea (1 mol) is condensed with 2 mols of aqueous formaldehyde by re-

Hunter (J.C.S., 1926, 2956) obtained an orange-red resin by treating phenylisocyanthiocarbamide with bromine in chloroform solution. *p*-Phenylisobutylthiocarbamide gave a red gum which changed to a crystalline mass, but resinified on treatment with ether.

fluxing, and an oil, which on continued heating forms a resin fusing at 50°C., separates. Organic solvents may replace water as the reaction medium. Benzaldehyde and di-o-tolyl-thiourea give a stable, whitish reaction product (m.p. 160-177°C.) that is soluble in ether, alcohol, benzene, chloroform, acetone and carbon disulphide, but not in water. A product<sup>52</sup> of viscous, or resinous, character may be prepared by heating ethylene or butylene glycol with thiourea. The latter is then boiled with formaldehyde under reflux. The thiourea can be replaced wholly or in part by urea, and other agents such as acetylaniline, cyclohexanone, benzylglycol and crotonaldehyde used instead of formaldehyde.

### THIOCYANATE COMPOSITIONS

As stated in the section on the production of thiourea, ammonium thiocyanate rearranges under the influence of heat to form thiourea. The conversion, however, is not complete; and, at 170°C., equilibrium is reached in about 1 hour, giving a mixture containing 25 per cent of thiourea.<sup>53</sup> Several investigators have prepared resins directly from formaldehyde and ammonium thiocyanate, others have used thiocyanates in conjunction with urea- or thiourea-formaldehyde condensations.

Ammonium thiocyanate combines with formaldehyde in concentrated aqueous solution in equimolecular proportions without production of carbon dioxide. The condensation product can combine with further quantities of formaldehyde, forming bodies which, however, are less stable and readily part with some formaldehyde. The products are amorphous yellow compounds without definite melting points and are practically insoluble except in strong acids and strong alkalies, which presumably decompose them into their components.<sup>54</sup>

Experiments conducted in the author's laboratory with ammonium thiocyanate and formaldehyde indicated a harder resin could be obtained by using formaldehyde in excess of equimolecular proportions. Ammonium thiocyanate was dissolved in the minimum amount of water required to put it into solution and admixed with aqueous 40 per cent formaldehyde solution, using equimolecular proportions. The mixture was heated to about 50°C. and the yellow solution became turbid. Then, a yellow resin precipitated. Water was poured off and the product was dried at 110°C. for several hours. When hot it was a yellow viscous liquid which solidified on cooling to an opaque light yellow mass. It was brittle and possessed a disagreeable odor. The resin was insoluble in alcohol, benzol, acetone and mixtures of these, either hot or cold. It was also insoluble in water. In aniline and phenol the resin dissolved and could be precipitated by adding alcohol or benzol. When two molecular proportions of formaldehyde were used the reaction progressed spontaneously after being started by gentle heating. The conversion proceeded with rising temperature and a hard amorphous precipitate formed and settled. This was collected and dried. It was found to be soluble in cresol on slight heating although there were some signs of decomposition. The odor of both of these resins when heated is very disagreeable.

Jacobson<sup>54</sup> prepared an acetone-soluble product that was compatible with nitro-

<sup>54</sup> Schmerda, *Z. angew. Chem.*, 1917, 30, 176; *J.S.C.I.*, 1917, 36, 942.

<sup>55</sup> R. A. Jacobson, U. S. P. 1,945,316, Jan. 30, 1934, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1934, 28, 2480. See also British P. 348,420, 1929, to Imperial Chem. Ind., Ltd.; *Chem. Abs.*, 1932, 26, 2070. L. H. Englund (U. S. P. 1,926,766, Sept. 12, 1933, to Victor Chemical Works; *Chem. Abs.*, 1933, 27, 5712) used ammonium thiocyanate in coating compositions designed to prevent the rusting of metal surfaces. E. Söderbäck (*Ann.*, 1928, 465, 184; *Brit. Chem. Abs. A*, 1928, 1229) found that an aqueous solution of sodium hydroxytetrahydrothiocyanate gels even at a 0.02 molar concentration.

cellulose by heating ammonium thiocyanate and formaldehyde. A solution containing 60 g. of ammonium thiocyanate, 360 g. of 37 per cent formalin and 15 cc. of 10 per cent hydrochloric acid is refluxed for 1-2 hours and then concentrated to about 145 g. A yellowish syrup is formed, insoluble in water and alcohol, but soluble in acetone. The acetone-soluble material may be incorporated with nitrocellulose to form coating compositions, or it may be rendered insoluble by heating at 100-110°C. for 6-8 hours. A composition containing casein, ammonium thiocyanate and paraformaldehyde was used by Pierson<sup>55</sup> as an adhesive in wood-working.

On refluxing 1 mol of ammonium thiocyanate with 1.5-2 mols of aqueous formaldehyde, a resin is formed that may be dried, powdered and molded.<sup>56</sup> The excess of formaldehyde is condensed with urea, thiourea or resorcinol, added just before the molding operation; and an alkyd resin is added as a plasticizer. Free sulphur usually separates in the initial condensation, but this is allowed to remain and functions as a filler. The molding powder is stable and can be stored.

Gams and Widmer<sup>57</sup> prepared a resin solution by boiling, in a neutral medium, 600 parts by weight (1 mol) of urea with 1500 parts by volume (2 mols) of 40 per cent formalin. To 200 parts of this solution, 30 parts by volume of a 10 per cent ammonium thiocyanate solution are added, and the mixture is poured into molds. After a few minutes the mass gelatinizes and hardens to a snow-white product (sp. gr. 0.8-0.9) on standing. Cellulosic textiles may be impregnated with soluble condensation products of formaldehyde and ammonium thiocyanate or ammonium sulphide in the presence of urea.<sup>58</sup> The treated material is dried and heated to complete the polymerization of the impregnant.

The addition of metal thiocyanates to urea-formaldehyde molding compositions is said to promote polymerization in the hot-press and improve the moldings.<sup>59</sup> Urea, aluminum thiocyanate and formaldehyde are heated together in the presence of an alkali, giving a mucilaginous precipitate. The incorporation of the condensation product of a metallic thiocyanate and formaldehyde with a urea-aldehyde reaction mixture has also been used in preparing a molding resin.<sup>60</sup> If acid salts are added to an evaporated reaction product of calcium thiocyanate, thiourea and formaldehyde, a yellow resin is precipitated.

## Chapter 32

### Modified Urea Resins. Resins from Urea Derivatives

As a class the resins made from urea and formaldehyde lack flexibility when hardened and for the most part are only sparingly soluble in organic solvents. In view of this, many suggestions have arisen concerning the problem of conferring greater toughness and flexibility on these resins by incorporation of other types. In some cases, no doubt, these added resins react with the urea resin group to form a complex. Since both urea and phenol react with formaldehyde, there have been numerous suggestions on methods of making composite resins in which a phenolic condensation product is a constituent. This has one disadvantage, namely, that although the urea resins are light-stable, the phenolic resins as a class are discolored on standing exposed to light. Other resins, therefore, have been tested, including the alkyd resins, which as a group are more stable to light than the phenolic resins. In addition there is a multiplicity of suggestions for use of various other resins, some of which are too costly to be utilized for the purpose and others have disadvantages of one sort or another. Since urea has been made on a large scale for fertilizer purposes, its low price in consequence makes possible the production of molding compositions at a cost comparable in a large measure with those made from phenolic bodies. Any addition, therefore, which tends to increase the cost to a considerable extent is barred for this reason. Likewise resins intended for use in lacquers should be made at a cost comparable with other lacquer resins of equivalent properties. These points should not be overlooked in the study of commercially available products.

#### UREA-ALDEHYDE RESINS WITH PHTHALIC ACID-GLYCEROL RESINS

Hill and Walker<sup>1</sup> averred that chemical combination occurred on mixing the two varieties of resin. Even a small proportion (5 per cent) of the urea-formaldehyde product produces in an alkyd resin a larger effect than they could account for by the formation of a physical mixture. The selection of the alkyd resin is determined by the purpose for which the final product is intended. If hardness is the only requisite, a straight glycerol-phthalic anhydride resin should be employed. The use of castor oil-alkyd products leads to stock intended for making flexible and light-colored lacquers. To make resins compatible with nitrocellulose esters, the proportions of the two types must be properly adjusted (in this case 70 parts of alkyd resin are used per 30 parts of dimethylolurea). Drying oils or drying oil acids are stated not to effect the hardenability of the resin mixture, but their use is detrimental to the color of the product.

The acidity of the reacting alkyd resin requires regulation and must not be too marked; although a small amount of acid serves as a hardening catalyst. Lacquers made with a resin containing upwards of 0.05 per cent of acid harden at room temperature, and similarly acid-catalyzed compound resins admixed with cellu-

<sup>1</sup> R. Hill and E. E. Walker, U. S. P. 1,877,130, Sept. 13, 1932; *Chem. Abs.*, 1933, 27, 200. British P. 344,401, 1929, to Imperial Chemical Industries, Ltd.; *Brit. Chem. Abs. B*, 1931, 597. French P. 694,181, 1930; *Chem. Abs.*, 1931, 25, 2013.

lose derivatives give films that are reported to become insoluble rapidly at ordinary temperatures. The acid catalysts used include sulphuric acid, hydrochloric acid, p-toluene sulphonic chloride, trichloroacetic acid and boric acid. Mixing of the two kinds of resin is performed in a solvent (ethylene chlorohydrin, dichlorohydrin, glycol monoethyl ether, butyl alcohol or cyclohexanol).

As an example of the method, 148 parts of phthalic anhydride, 62 parts of glycerol and 150 parts of castor oil are heated at 190-200°C. for 3-4 hours, while a current of carbon dioxide or nitrogen is passed through the reaction mixture. The resulting resin is a tough, flexible, moderately hard substance that is soluble in ketones, esters, hydrocarbons and hot alcoholic solvents. A solution of 14 parts of this resin in 14 parts of butyl alcohol is prepared, and the  $p_H$  of the liquid is adjusted to 6. Next, 3 parts of urea are added, heat being applied to complete solution, and 3 parts of para-formaldehyde are introduced into the hot mixture. After refluxing for the completion of the aldehyde reaction, the solution is diluted with 10 parts of solvent naphtha and filtered to remove suspended matter. The resulting lacquer gives transparent, colorless coatings after baking. The resin itself, which is compatible with nitrocellulose, may be isolated by solvent-evaporation *in vacuo* at low temperatures. Brown lacquers are obtained when linseed oil fatty acids are added to the resin composition.

If 100 parts of the prepared alkyd resin are dissolved in 200 parts of glycol monoethyl ether with 100 parts of dimethylolurea, reaction occurs on refluxing for a half hour. Methylated spirits (85 parts) and toluene (85 parts) are added, and the lacquer is clarified by filtration. The addition of this lacquer to a nitrocellulose solution containing small amounts of sulphuric acid gives a coating composition that dries in slightly over one hour at room temperature after application. The acids already mentioned confer on these resins the property of hardening in the cold.

To save the cost of expensive solvents, polyhydric alcohol-polybasic acids may be used as aqueous emulsions for coating purposes, and urea-formaldehyde resins can be incorporated with effects resembling those produced when solvents are employed.<sup>3</sup>

Thus, 8 parts of a urea-formaldehyde resin (prepared from 2 mols of formaldehyde and 1 mol of urea with boric acid as a catalyst) and 0.25 part of ammonia are mixed with 95 parts of water. Then, 40 parts of an alkyd resin, prepared by heating 31 parts of glycerol, 74 parts of phthalic anhydride and 75 parts of castor oil for 3-4 hours at 190-200°C., are dissolved in 32 parts of solvent naphtha and 28 parts of butyl alcohol with 4 parts of oleic acid. The two solutions are vigorously mixed, forming an emulsion that may be applied to material (e.g., rubber or leather cloth) and is hardened by heating at 115°C. for 2 hours.

Goldschmidt and Mayrhofer<sup>2</sup> recommended the addition of the liquid or viscous product obtained from phthalic anhydride and polyhydric alcohols to an aqueous mixture of urea and formaldehyde. The addition may be made prior to, during or after an alkaline or acid condensation. The ratio of urea to phthalic anhydride must be considerably greater than 1. Transparent, vitreous products, that can be hardened in molds without cracking at a higher temperature than normally, are obtained. Synthetic resins of this class were also studied by Jaeger.<sup>4</sup> Although less readily obtainable compounds will give much the same results, glycerol and glycol are the most important polyhydric alcohols used, and phthalic anhydride is the principal acidic ingredient. A large variety of monocarboxylic acids (including abietic acid, cinnamic acid, linolenic acid, rape oil acids, stearic acid, whale oil acids and furoic acid) and the usual plasticizers and fillers may be incorporated in the

<sup>2</sup> S. Goldschmidt and R. Mayrhofer, British P. 316,144, 1928; *Chem. Abs.*, 1930, 24, 1711. German P. 572,367, 1923; *Chem. Abs.*, 1925, 27, 3044.

<sup>4</sup> A. O. Jaeger, U. S. P. 1,890,093, May 24, 1932, to Selden Co.; *Chem. Abs.*, 1932, 26, 3945. U. S. P. 1,941,474, Jan. 2, 1934; *Chem. Abs.*, 1934, 28, 1890.

resins. In an example of Jaeger's method of making a powder for molding tableware, a resin is first prepared by heating 1 mol of phthalic anhydride, 1 mol of glycerol, 0.5 mol of phthalide and 0.5 mol of benzoic acid at 180-210°C. From 1.5 to 2 parts of this resin are mixed with 1 part of a urea- or thiourea-formaldehyde condensation product and a small amount (2-6 per cent) of a plasticizer (toluene sulphonamide). The composite resin is then ground with cotton flock or wood flour to form the molding powder. The molded article is milky-white and is said to be less brittle than exclusively urea-formaldehyde products. A phenol may also be used in preparing these resins.<sup>5</sup>

Ellis<sup>6</sup> has shown that phthalic acid, alone, is capable of acting as a catalyst in urea-formaldehyde condensations carried out at, e.g., superatmospheric pressures. Lougovoy<sup>7</sup> examined the effect of a large number of organic acids on this reaction. It appears that phthalic acid actually combines to a large extent in the resin, which contains little free acid unless a large excess is used initially. Such a resin is readily formed by refluxing 50 parts of urea, 50 parts of phthalic anhydride and 150 parts of aqueous formaldehyde and then evaporating. The products range from syrups, that are miscible with alcohols or ketones and are useful as varnishes and impregnating agents, to glassy solids. The solid products can be molded with fillers and can also be applied to the making of glass substitutes.

By fusing urea with phthalic anhydride and then reacting the product with formaldehyde, Bitterich<sup>8</sup> obtained a clear resin which could be molded or dissolved to form a varnish. As an example, 50 kg. of phthalic anhydride and 40 kg. of urea are fused and held molten for a time at 200°C. After cooling the mass to 80°C., 80 kg. of 40 per cent formalin are added and the reaction is completed by heating for a half hour at 110°C. Water may be removed by distillation *in vacuo*. Acid catalysts may be employed and the fusion can be carried out in a high-boiling solvent.

A glycerol ester of phthalic acid may be fused and mixed with lithopone, sawdust, urea and paraformaldehyde, forming a mass that is brittle when cold.<sup>9</sup> After disintegration, the composition is hot-pressed.

#### RESINS FROM UREA WITH ALCOHOLS OR KETONES

Urea and other organic amines were employed by Burke<sup>10</sup> as accelerators of the polymerization of ketone-formaldehyde condensation products (see Chapter 25) in conjunction with fillers and other modifiers. The products are used with pyroxylin for coating compositions.

Paquin's investigations<sup>11</sup> in this field concerned the condensation products of urea and thiourea (or their derivatives) with alcohols or ketones, many of which condensates were capable of further reaction with aldehydes. Urea and its derivatives normally condense with alcohols or ketones to form well-defined crystalline substances, but prolonged interaction was found to give oily or resinous products.<sup>12</sup> Other amino compounds may be employed in the condensation, but in any case the resulting products react further with aldehydes. By heating 139 parts of ethyl alcohol and 60 parts of urea for 5 hours at 180-190°C. under pressure, an oil is

formed. The oil is separated from its content of urethan and allophanic esters by vacuum distillation and is soluble in water and organic solvents. Urea (60 parts), benzyl alcohol (200 parts) and glycerol (6 parts) form a similar, viscous oil, soluble in organic solvents. A water-soluble oil, that is purified by fractional distillation, is prepared also by heating 240 parts of ethylene glycol and 96 parts of thiourea for 1.5 hours at 190-200°C. A light-yellow resin is obtained by refluxing 327 parts of cyclohexanone and 200 parts of urea for 1.25 hours in an apparatus heated with water at 90°C. The clear resin (100 parts) may be further

*Courtesy Bakelite Corp.*

FIG. 112.—A Rotary Preforming Machine which Compresses Tablets into Proper Shape for Molding.

refluxed with 70 parts of 35 per cent formaldehyde, yielding a limpid product after expelling water. Toluene sulphonamide is also used in these reactions.<sup>13</sup>

Metals react with these products, giving substances with high viscosities and improved solubility in water.<sup>14</sup> Thus, 180 parts of butylene glycol are heated in a reflux apparatus with 80 parts of urea and 5 parts of metallic calcium. Hydrogen is evolved and, after 45 minutes, a yellow, viscous oil is obtained. Zinc, cadmium and similar metals, introduced during or after the completion of the reaction between the urea and the alcohol or ketone, are also dissolved with evolution of hydrogen. These oils and resins are useful as softening agents for casein and gelatin.

<sup>14</sup> M. Paquin, German P. 510,428, 1927, addn. to 506,963, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1931, 25, 1400. German P. 512,831, 1927, addn. to 510,428; *Chem. Abs.*, 1931, 25, 1400. British P. 290,192, 1928, addn. to 278,890; *Brit. Chem. Abs. B*, 1929, 709.

The urea-alcohol or ketone reaction requires no external heat when allowed to take place in the presence of strong mineral acids.<sup>15</sup> As an example, 192 parts of 1,3-butyleneglycol are mixed with 120 parts of urea and 8 parts of concentrated sulphuric acid. During this operation, the temperature gradually rises to 40-60°C. and a clear solution is obtained. After stirring for 5 hours, a viscous, oily product is formed, which is freed from acid and purified by vacuum distillation. The condensation products of urea or its derivatives with an alcohol or ketone improve the dispersion of dyes in dye pastes and printing compositions and prevent the formation of crusts.<sup>16</sup>

The formation of resins (as opposed to oily products) in this group of reactions depends on length of heating or on the presence of an aldehyde (notably formaldehyde). Prolonged heating will probably convert any of the oils mentioned to resins, but this result is achieved more readily by the use of aldehydes. Thus, butylene glycol, urea and formaldehyde give a clear, resinous mass when heated together.<sup>17</sup> If a low temperature is employed, the products are generally soluble in water or alcohols.

Paquin<sup>18</sup> described a lacquer composed of bronze powder mixed with a vehicle obtained by reacting urea with a cyclic acetal derived from glycerol and acetaldehyde.

Urea or its derivatives will also condense with polyvinyl alcohol and other highly polymerized alcohols.<sup>19</sup> The polyvinyl alcohol may be condensed with an aldehyde (formaldehyde) and simultaneously or subsequently reacted with phenol, urea or aniline.<sup>20</sup> Alternatively, the alcohol is condensed with a methylol compound (urea-formaldehyde or phenol-formaldehyde). The products are useful for sizes, emulsions or molded articles.

The two-stage, urea-formaldehyde process (see Chapter 27), wherein methylol-urea is first isolated, renders it possible to obtain resins of modified properties. Thus, by heating methylolurea (or methylolthiourea) or its polymers with a compound containing at least 2 free hydroxyl groups, water-soluble resins are obtained.<sup>21</sup> Such products, best condensed by acid in the presence of a buffer, serve as sources of artificial horn or casein.<sup>22</sup>

Alternatively, the urea-formaldehyde condensation may be performed in the presence of excess of a compound containing at least 1 free hydroxyl group and another reactive group (the amino or carboxyl group). The later reaction of this additional group can be used to modify the product. Pungs, Eisenmann, Scholz and Kollmann<sup>23</sup> have investigated the production and utilization of these modified types. The additional group in the condensate may be reacted with organic compounds capable of forming an oxygenated linkage (alcoholates, phenols, phenolates, alkylene oxides and acid chlorides or anhydrides). The reagents containing one or more hydroxyl groups and an additional reactive group include ethylene chlorohydrin, glycerol  $\alpha$ -monochlorohydrin or  $\alpha,\beta$ -dichlorohydrin and esters of polyhydric alcohols with polybasic organic acids, as, e.g., esters of phthalic acid, oxalic acid, succinic acid, adipic acid or tartaric acid of the type

(in which R represents an aliphatic, cycloaliphatic or aromatic hydrocarbon radical, x and y are any whole numbers and n may be zero or a whole number) or esters of benzoic (or other monobasic aromatic or aliphatic, saturated or unsaturated acids) with polyhydric alcohols.

The condensation of monomethylolurea with glycol proceeds according to the scheme:

The resulting compound gives an ester on further reaction with acetyl chloride,

an ether with sodium methylate,

a diester with the acid methyl ester of oxalic acid,

and an ester-ether with glycol monoacetate,

The reaction of monoethanolamine with monomethylolurea is as follows:

The substance obtained reacts further with acetyl chloride giving an amide,

and with the acid methyl ester of oxalic acid giving an ester-amide,

Similarly, a methylolurea may react with a hydroxy-carboxylic acid (HOR-COOH) with the formation of an ether or ester group. The remaining carboxyl or alcoholic group is then further reacted. In each case the products correspond to the general formula

in which  $x$  is an integral number greater than 1,  $Z$  denotes oxygen or sulphur,  $\text{R}'$  indicates an alkyl radical (in which hydrogen atoms may be replaced by oxygen, ether or ester radicals) containing at least 2 carbon atoms and which is linked through  $\text{X}$  (an ether oxygen atom, a carboxyl group, an amine group or a carboxylic amide group) to a hydrocarbon radical,  $\text{R}''$ .

The reaction is usually performed with the halogen substitution products of the polyhydric alcohols, and the halogen content of the reaction products is determined to measure the amount of alcoholate or sodium salt necessary for the subsequent etherification or esterification. When used in excess, the reaction components serve as solvents. The separation of any excess can be carried out, before the conversion of the reactive groups in the primary products, by precipitation of the condensate or by steam distillation.

In an example outlined in the investigations of Pungs, Eisenmann, Scholz and Kollmann,<sup>24</sup> 80 cc. of a 5 per cent (by weight) ethyl alcohol solution of urea nitrate are added to 1200 g. of ethylene chlorohydrin at 95°C., 800 g. of dimethylolurea are then slowly introduced while stirring, and the whole is stirred for a further 20 minutes at 90°C. After cooling the solution, neutralizing with tertiary sodium phosphate and filtering, 5 times its volume of 95 per cent ethyl alcohol is added while stirring vigorously, the condensation product thus separating in a powdery form. The powder is washed with ether and dried *in vacuo* at 40-50°C. The substance contains 9 per cent of chlorine. The alcohol-precipitated product (250 g.) is dissolved in 600 g. of ethylene glycol monomethyl ether, and 200 g. of the sodium soap of linseed oil

<sup>24</sup> *Loc. cit.* See also K. Eisenmann, E. Scholz and K. Wolf, German P. 588,426, 1933, to I. G. Farbenind. A.-G.; *Chem. Abn.*, 1934. 28. 1560.

fatty acids are added to the solution. The reaction mixture is then heated at 120°C. for 12 hours with stirring and separated from precipitated sodium chloride. The reaction, which is carried out with a quantity of sodium soap slightly exceeding that required for esterification, proceeds practically quantitatively. The small amount of soap still present is removed by careful neutralization with a few drops of glacial acetic acid, the linoleic acid set free being then dissolved in the ether. By mixing the solution with 5-6 times its volume of ethyl ether, the condensation product is precipitated. After repeated washing with ether and drying, a yellow-brown resin having an appearance similar to linoxyn is obtained. The resin probably corresponds to the formula:

<sup>a</sup> R is the linseed oil radical.

In another example, 100 parts of adipic 1,1'-diglyceride (prepared by the reaction of the sodium salt of adipic acid with  $\alpha$ -monochlorohydrin) are diluted with 40 parts of dioxane, heated to 90°C. and treated with 0.7 part of concentrated hydrochloric acid, 50 parts of dimethylolurea being then added with stirring. After stirring for half an hour at 90°C., the reaction mixture is neutralized with tertiary sodium phosphate, and the condensation product is precipitated from the filtered and cooled solution by the admixture of 8 times its volume of 95 per cent ethyl alcohol. The dried, pulverized product (6 parts by weight) is suspended in 100 parts by weight of pyridine. To this suspension, 6 parts of benzoyl chloride are added, and the mixture is stirred while being cooled with ice until the reaction is complete. The reaction mixture is then poured into water; a pale-yellow oil separates and is washed with water. An ethylene glycol monomethyl ether solution of the oil leaves on a substratum after drying a colorless, firmly adherent film that may be hardened at elevated temperatures (100-120°C.). The product also possesses great adhesive power and probably corresponds to the following formula

In an additional example, 450 parts of glycerol are kneaded with 5 parts of oxalic acid and 900 parts of dimethylolurea and heated to 100°C. for 2 hours. The resulting, hard, white mass is pulverized in a mill, and 175 parts of the disintegrated substance are dissolved at 100°C. in 200 parts of distilled, commercial cresol.<sup>25</sup> After cooling to 80°C., 4.5 parts of phosphorus pentoxide are added with stirring, raising the temperature to 95°C. After 1 hour at 95°C., the resulting product, which is a tough, syrupy mass upon cooling, is washed with hot water (until the water remains neutral) and is freed from a remainder of cresol by treatment under diminished pressure with steam heated to 130°C. Water is removed by fusing *in vacuo* at 110°C., giving a clear, yellow resin which may be represented by the formula

<sup>25</sup> Pure m-cresol can be obtained from a mixture of cresols by treating with urea, separating the addition product and decomposing it with dilute mineral acids (French P. 660,091, 1928, to Schering-Kahlbaum A.-G.; *Chem. Abs.*, 1930, 24, 130. British P. 297,083, 1928; *Brit. Chem. Abs.* B, 1929, 973).

The products of the various methods can be processed, by themselves or in admixture with substances including cellulose derivatives, natural or synthetic resins, softening agents, fillers and coloring materials, to form lacquers or plastic masses. An adhesive for abrasives may also be produced from the acid condensation of methylol derivatives of urea with hydroxylated esters of fatty acids, containing at least 10 carbon atoms, in the presence of a monohydric alcohol as solvent<sup>28</sup>. The resinous product, after a heat treatment at 80-130°C., is soluble in esters, ketones and aromatic hydrocarbons.

Luther<sup>27</sup> obtained clear, water-soluble masses by heating methylolureas with a polyhydric alcohol. A suspension of 500 parts of dimethylolurea in 700 parts of glycerol together with 20 parts of acid potassium oxalate are heated to 100-110°C. until a clear solution is obtained. If the solution is neutralized by means of an alkali-metal carbonate and filtered, a viscous product is formed which can be employed as a plasticizer for gelatin.

#### FURFURAL-UREA RESINS

Black, lustrous resins resembling ebonite are produced by the acid condensation of urea and furfural. Kappeler<sup>29</sup> prepared these resins by mixing 3 parts of urea (1 mol), 3 parts of 38 per cent hydrochloric acid and 1-3 parts of water with 5 parts of furfural (1 mol). The liquid becomes dark and is poured into molds, in which a lively reaction soon begins. The molds are cooled until the reaction moderates. When interaction ceases, the solid obtained is gradually heated to 100°C., giving the ebonite-like resin that is insoluble in the usual solvents, infusible and unaffected by alkalis or dilute acids. The resin becomes tougher on being baked with an impregnating agent (linseed oil). If alcohol, glycerol or acetone is substituted for water in the reaction, the resulting products possess a higher luster. The liquid mixture, prior to reaction, may be used for impregnating wood or cellulose.

A mixture of 3 parts of urea with 1 part of aniline, toluidine or other amine can be used to replace urea in the process. Aniline, p-toluidine, p-phenylenediamine and  $\alpha$ - and  $\beta$ -naphthylamine yield resins with furfural and urea.<sup>30</sup> Furfural may be replaced with a mixture of furfural and another aldehyde. Thus, a mixture of 4 parts of furfural and 2 parts of 40 per cent formaldehyde may be employed. The initial condensation of urea (3 parts) and furfural (5 parts) can be carried out at 100°C. in the absence of acid, giving a yellow resin that blackens and hardens on further heating with hydrochloric acid. Condensation of the reactants is also possible with 30 per cent sodium hydroxide solution. The product prepared in this manner is soft and soluble, but the black substance is again obtained when the condensation is completed with hydrochloric acid. In these reactions, furfural may also be replaced by furfuramide, and thiourea substituted for urea. Additions of coloring matter, sawdust, cork powder, leather powder, heavy spar, asbestos, glycerol, camphor, naphthalene, ketones, phenols and amines can be included in the resin composition.

In their investigations of urea-furfural resins, Novotny and Johnson<sup>30</sup> found that

<sup>30</sup> E. E. Novotny and W. W. Johnson, U. S. P. 1,827,824, Oct. 20, 1931, to J. S. Stokes; *Chem. Abs.*, 1932, 26, 862. U. S. P. 1,931,526, Mar. 20, 1934; *Chem. Abs.*, 1934, 28, 3606.

prolongation of condensation in the presence of hydrochloric acid gave products tending to become powdery and friable and that a small amount of a basic compound was a better catalyst for the reaction. With sodium carbonate or ammonia as catalyst, the condensation at 138°C. is readily controlled. Thus, a mixture composed of 100 lb. of urea, 300 lb. of furfural and 4 lb. of 26 per cent ammonia is refluxed at 104°C. for 2 hours, after which time the water and excess reactants are removed by distillation. During the distillation, the temperature should not exceed 158°C., or the substance will become hard and infusible. If overheating is avoided, the resulting resin is soluble in alcohol, acetone and ether, but insoluble in benzene and water. These soluble resins are useful as varnishes for impregnating paper, cloth and asbestos. After the solvents have been evaporated, the products are hot-molded to harden the resin, the hardening process being facilitated by formaldehyde. The hardened material possesses considerable mechanical strength and high dielectric properties.

Dry potassium or sodium carbonates, taken in quantities equivalent to 1 per cent of the total urea and furfural, are recommended by Novotny and Johnson to catalyze the reaction. A small amount (3 per cent) of a 20 per cent aqueous solution of potassium or sodium hydroxide may serve as a condensing agent.

Various modifying agents, including tung oil, lanolin and camphor can be added to the reacting mass. With 5 per cent of tung oil, the furfural-urea products have increased flexibility. A similar proportion of lanolin can be incorporated after the condensation reaction is completed and gives a resin intended for cold-punching.

#### ACROLEIN-UREA RESINS

Reaction between acrolein and urea occurs readily, its course depending on the relative proportions of the reactants, on the temperature and on the presence of catalysts, solvents or diluents. Gams and Widmer<sup>21</sup> made a study of the influence of the various conditions on the reaction. They found that if the proportions were 0.5 mol of aldehyde to one of urea, a highly viscous syrup could be obtained. With 0.75 mol of acrolein to 1 mol of urea, gelatinous substances are formed, and larger proportions of acrolein give vitreous, solid products. Without catalysts or solvents, the reaction is slow at ordinary temperatures, and it is best carried out in a closed vessel above the boiling point of acrolein (52°C.). The process occurs fairly quickly, even below 50°C., with a catalyst, and the reaction mixture must be cooled to prevent too violent an interaction. The catalysts used are inorganic or organic acids or bases, including sulphuric acid, acetic acid, sodium hydroxide solutions, ethylene diamine and acid or basic salts. Solvents, particularly when low temperatures are employed, advantageously facilitate the starting of the reaction, although the whole of the urea need not be dissolved. Water, methyl alcohol, ethyl alcohol and glycerol are employed as solvents or diluents and may be separated from the products at the conclusion of the reaction.

The urea-acrolein condensation can be performed in two stages. The first stage, using 0.5 mol of acrolein per mol of urea, yields the viscous, syrupy substance, which, in the second step, is converted to a gelatinous or hard material by merely adding additional acrolein. Formaldehyde can replace acrolein in the hardening process. Thiourea, methylurea and other urea derivatives can be sub-

<sup>21</sup> A. Gams and G. Widmer, U. S. P. 1,654,215, Dec. 27, 1927, to Soc. anon. pour. l'ind. chim. à Bâle; *Chem. Abs.*, 1928, 22, 849. German P. 554,552, 1925; *Chem. Abs.*, 1932, 26, 6081. British P. 280,288, 1925; *Chem. Abs.*, 1927, 21, 3432. See also C. Marx, *Plastics*, 1928, 4, 194.

stituted for the urea, and similarly acrolein itself can be replaced by acrolein polymers (disacryl or acrolein resins).

Specifically, if 12 parts of urea are heated with 11.2 parts of acrolein for about 1 hour at 100°C. in a closed vessel, a transparent, vitreous product results. On heating 12 parts of urea, 5.6 parts of acrolein and 0.03 part of glacial acetic acid for one hour at 80°C. in a closed container, a highly viscous, transparent mass is obtained. In another example, 60 parts of urea, 5 parts of water and 0.8 part of 1 per cent sulphuric acid are condensed with 56 parts of acrolein at 40-50°C. The resulting clear syrup is cooled for some hours and allowed to stand at ordinary temperatures until a solid jelly forms. In an example of the use of acrolein resins, 5 parts of a wax-white resin (made from acrolein by alkaline condensation) are condensed with 2 parts of urea at 100°C. A soft, yellowish resin is produced, and this can be hardened by further additions of urea.

The viscous syrups produced in these condensations serve as adhesives and varnishes. The hardened, vitreous products, because they are easily sawn, bored, cut, polished or shaved and are resistant to chemicals, are used for making all sorts of shaped objects. For special purposes, dyestuffs, fillers and agents imparting extra elasticity are added to the resins.

#### CONDENSATION WITH OTHER ALDEHYDES

The cost of formaldehyde and the instability (over long periods) of the initial condensation products were pointed out by Barsky and Wohnsiedler<sup>22</sup> as disadvantages of urea-formaldehyde resins. Hence, the investigators prepared a resin in which part of the formaldehyde was replaced by acetaldehyde. Thus, 300 parts of urea are dissolved in 510 parts of water, and 231 parts of acetaldehyde are added at 20-30°C. After adding 200 parts of 0.5 *N* hydrochloric acid, the mixture is allowed to stand for from several days to 1 week at 20-30°C. The resulting precipitate of ethylidene urea is filtered, and 22 parts of it are mixed with 30 parts of 38 per cent formaldehyde and 15 parts of water. A small quantity of 0.5 *N* hydrochloric acid (0.2 part) is introduced, and the mixture is boiled to effect solution. This solution gives a clear, water-soluble resin, if made alkaline with sodium hydroxide and concentrated; or it gives a water-insoluble product by means of concentration and a heat-hardening treatment at 70°C. An aqueous solution of the water-soluble resin is used to impregnate paper or fabric and is then made insoluble by an acid treatment.

The products can be cast or molded or incorporated with fillers to form molding powders. As an example, a mixture of 43 parts of ethylidene urea, 40 parts of 38 per cent formaldehyde, 25 parts of water and 2 parts of 0.5 *N* hydrochloric acid is refluxed and filtered. The clear syrup (94 parts) is incorporated with 27 parts of disintegrated paper pulp and dried to yield 75 parts by weight. When ground, this product forms a powder that can be molded at 145-160° under pressure.

The oxidation of petroleum hydrocarbons by air or an oxygen-containing gas furnishes a complex mixture of aldehydes which Ellis<sup>23</sup> used for direct combination with urea or thiourea. The aldehyde mixture is heated with urea for several hours until a syrupy liquid, useful as an impregnant, forms. Further heating transforms the syrup into a resin, but the latter is liable to have an acrid odor that should be removed by stronger heating or steaming.

Schmidt<sup>24</sup> described the use of aryl thioureas for reaction with formaldehyde,

<sup>22</sup> G. Barsky and H. P. Wohnsiedler, U. S. P. 1,896,276, Feb. 7, 1933, to American Cyanamid Co.; *Chem. Abs.*, 1933, 27, 2831.

<sup>23</sup> Carleton Ellis, U. S. P. 1,952,060, Mar. 27, 1934, to Ellis-Foster Co.; *Chem. Abs.*, 1934, 28, 3606.

<sup>24</sup> J. G. Schmidt, U. S. P. 1,919,135, July 18, 1933, to E. F. Houghton & Co.; *Chem. Abs.*, 1933, 27, 4814.

acetaldehyde and benzaldehyde to form resins (see Chapter 29). Wayne<sup>35</sup> prepared a water-soluble resin with emulsifying and wetting properties by condensing 1 mol of aldol with 1 mol of urea at 110-120°C.

#### PHENOLIC SUBSTANCES AS MODIFYING AGENTS

In a study of phenol-urea-formaldehyde condensations, Barthélemy<sup>36</sup> found that on the addition of aqueous alcohol to an alcoholic solution of the partially condensed product, a mixture of 2 colloidal suspensions is obtained. These suspensions can be separated into positive and negative components by the action of an electric field. The further condensation of the reactants depends on the nature of the catalytic ion and solvent employed and on the temperature.

Ellis<sup>37</sup> prepared an aldehyde-phenol-urea resin by first heating 210 parts of phenol and 150 parts of aqueous formaldehyde for 2 hours in an autoclave under a pressure of 100 lb. and at a temperature of 138-143°C. On completion of the reaction, water is removed, giving a fusible and alcohol-soluble resin. Well-dried dimethylolurea (1 part by weight) added to 10 parts of the phenolic resin raised the melting point of the latter substance. By adding increasing amounts of urea-formaldehyde condensation products, a range of molding powders can be obtained.

The fusible condensation product of furfural with excess of phenol in the presence of a small quantity of hydrochloric acid can be incorporated with varying amounts of dimethylolurea. Dimethylolurea was also found capable of incorporation with phenol-sulphur resins. As an example, 1 part of phenol is treated with 2-2.5 parts of sulphur monochloride, yielding a resin which is combined with 10 per cent or more of dimethylolurea. Additions of sulphur resins make the material more readily fusible and capable of flowing freely under combined heat and pressure, thus yielding a sharp impress during the molding operation.<sup>38</sup> A molding composition is also prepared by combining dimethylolurea with a phenol-furfural resin.

A light-stable, moldable product is made by condensing urea with a small amount of phenol and a large excess of formaldehyde.<sup>39</sup> After adding an excess of phenol and further amounts of formaldehyde, the mass is made alkaline, and water is distilled off *in vacuo* at 50°C. An organic acid (lactic acid) is added to neutralize the alkali, and the reaction water is removed *in vacuo* at 75°C. Lastly, the condensation product is molded and hardened at 80°C.

A condensation product of urea, formaldehyde and a phenol was prepared by Terwilliger<sup>40</sup> who found that it possessed greater water-resistance than urea resins. With an addition of only 5 per cent of phenol, the water absorption by a particular urea-formaldehyde resin was reduced to a half or less. Increase of phenol content raised the water-resistance, but 10 per cent of phenol was considered most efficient in this respect. Furthermore, the addition of phenol tended to reduce formaldehyde losses. In an example of the process, 40 parts by weight of urea are dissolved in 100 parts of a 40 per cent formaldehyde solution. The mixture is neutralized with ammonia, sodium hydroxide or calcium hydroxide until just acid to litmus, heated to 50°C. and filtered. The filtered solution is refluxed for 30 minutes and then evaporated until the initial boiling point of 97°C. is raised to 100-101°C., during which about 65 per cent of the water is removed. Phenol

<sup>39</sup> German P. 557,549, 1927, to "Herold" A.-G.; *Chem. Abs.*, 1933, 27, 575.

<sup>40</sup> C. O. Terwilliger, U. S. P. 1,678,024, July 24, 1928, to F. v. Briesen; *Chem. Abs.*, 1928, 22, 3499.

(2 parts) is stirred into the hot solution which is then placed in a drying oven and kept at 75°C. for 2-3 hours, then at 85-95°C. for 4-5 hours and finally at 110°C. until hard.

Bender<sup>41</sup> prepared a resin by reacting a phenol with more than an equimolecular proportion of formaldehyde in the presence of a basic catalyst and by combining the excess aldehyde with urea or other resin-forming agents (thiourea or p-toluenesulphonamide) with the aid of an acid catalyst. In the method, 145 parts of phenol and 412 parts of 40 per cent formaldehyde solution are heated with 1-5 parts of sodium carbonate as catalyst. Water is separated by evaporation under reduced pressure, and most of the excess formaldehyde dissolves in the resin as paraform. Then, 40 parts of urea are added together with sufficient lactic acid or phosphoric acid to make the mass acidic. Heating is continued to complete the urea-formaldehyde reaction, and a solvent is added at this point

Fig. 113.—Paper-Shredding Machine Used in Preparing Fillers for Molding Compositions.

if a varnish or lacquer is the desired end product. The proportions used in the process should not be greater than 1 mol of urea for each 2 mols of residual paraform. The resins can be employed in the manufacture of transparent or colored articles, lacquers, enamels and white molding compounds. This type of resin was used by Lloyd<sup>42</sup> as a binder for mica sheets and tubes. Bender<sup>43</sup> also described the production of laminated products using these resins as binders or impregnating agents. The absence of any appreciable amount of free phenol or free formaldehyde in the binder gives the molded articles a light color. The odorless nature of these resins make them useful in the production of articles coming into contact with foodstuffs.

Another way of preparing phenol-urea-paraform resins was described by Crump and Lloyd<sup>44</sup> who melted the three constituents together without the aid of aqueous solution and completed the condensation by heating. The proportion of urea used is greater than that of the phenol, and the reaction mixture is kept neutral or

alkaline. The resins can be ground to a fine powder and are easily fusible, but become infusible on further heating. Goldschmidt and Neuss<sup>48</sup> heated urea and formaldehyde with an organic compound of acid character (phenol) that is capable of forming resinous products with formaldehyde. With small amounts of acid condensing media, clear or dull bodies were produced, according to the proportions of urea and aldehyde used. If larger amounts of acid media are employed, meerschäum-like substances are obtained. For example, 10 g. of phenol mixed with 94 g. of 30 per cent formaldehyde and 0.096 g. of concentrated sulphuric acid are refluxed, 20 g. of urea added and heating is continued until a thick, viscous mass results. After cooling and removing water by pressing, the material is hardened and dried, yielding a compact, waterproof, ivory-like product. The use of the acid condensing medium is said to effect a 15-17 per cent saving of formaldehyde. Neuss<sup>48</sup> also used resorcinol to replace phenol.

Resorcinol and analogous phenols were used by Howald<sup>49</sup> to modify urea-formaldehyde resins. The urea and formaldehyde are condensed in aqueous solution, water is removed and resorcinol is mixed with the dried condensation product. Quinol, orcinol, pyrogallol and phloroglucinol give similar results. The molded articles prepared with the use of resorcinol are not quite water-white, but they can be delicately tinted by incorporating dyes in the initial aqueous mixture.

Potter and Crump<sup>50</sup> developed a method for converting the intermediate products of the urea-phenol-formaldehyde condensation directly into the final hardened form by means of hardening agents. The first stage of the process consists in the combination of the 3 reactants by means of heat, followed by a dehydration which gives a syrupy resin.<sup>50</sup> The speed with which this resin will harden in a mold depends on the proportion of phenol to urea in the original syrup and on the nature and amount of the hardening agent. The hardening agents used include strong inorganic or organic acids and salts capable of conditioning an acid reaction (aniline hydrochloride, urea nitrate or ammonium chloride). The larger the ratio of urea to phenol, the more rapid is the hardening. By adding 10 per cent (calculated on the weight of the syrup) of urea nitrate to a syrup prepared from 100 parts of phenol, 34 parts of urea, 185 parts by volume of 40 per cent formaldehyde and 0.01 part by weight of oxalic acid, the first hardening phase is completed in 1 minute, and the resin becomes permanently hard and infusible in 1 hour.

Acid condensing agents have been utilized by a number of other investigators in the preparation of resins of this type. Nakamura<sup>51</sup> made a colorless and transparent resin by condensing phenol and formaldehyde in the presence of an acid catalyst and from 25 to 80 per cent of a urea-formaldehyde condensation product. The mixture can be dried and hardened at 80-130°C. A milk-white color is imparted to the resin by adding stearic or oleic acid or camphor oil. In making

<sup>53</sup> M. Nakamura, U. S. P. 1,775,135, Sept. 9, 1930, to Sankyo K. K.; *Chem. Abs.*, 1930, 24, 5173.

similar resins, Crump<sup>51</sup> slowly added urea dissolved in part of the aldehyde to a solution of the phenol in the remainder of the formaldehyde, kept at the boiling point. Water and uncondensed reactants were removed from the initial condensation product (still in a soluble form) by distillation *in vacuo* in the presence of a neutral dehydrating agent capable of forming a constant-boiling mixture with water (e.g., butyl alcohol), followed by open-pan boiling. An alkaline condensing agent may be added toward the end of the condensation and an acid catalyst (oxalic acid) during the vacuum distillation. The ratio of phenol to urea may vary from 0.5:1 to 5:1, the lower ratios giving products for the manufacture of molded articles and the higher ones for the production of varnishes. Rothera, Blythen and Gillespie<sup>52</sup> described a resin prepared by warming urea or a urea derivative with an aldehyde for a short time, and then heating the primary reaction product with phenol or naphthol in an acid medium until solids in the form of resins are precipitated. Spitzer<sup>53</sup> precipitated plastic masses from colloidal solutions of resinous condensation products (from aldehydes and phenol or cresol) by the addition of urea-formaldehyde hydrosols. In another method, plastic substances are prepared by condensing urea with formaldehyde in the presence of phenol or a di- or polyphenol; rubber-like compositions being obtained on oxidation with a persulphate during or after condensation.<sup>54</sup> Cameron and Jackson<sup>55</sup> heated 1 mol of cresol at 100°C. with 2 mols of paraformaldehyde in the presence of triethanolamine, a dispersing agent (potassium bromide), urea and guanidine carbonate. The mixture is chilled rapidly to room temperature, and a liquid resin, that can be cured by heat, is formed. Melamid<sup>56</sup> submitted products obtained by condensing ketones and phenols with urea to a further condensation with aldehydes.

A colorless, transparent resin is formed by condensing phenol and formaldehyde in the presence of alkaline catalysts, acidifying and then adding a solution of urea in 40 per cent formaldehyde.<sup>57</sup> Thiourea is used to clarify the final product, and the initial condensation can be made with an acid catalyst. Ostersetzer and Riesenfeld<sup>58</sup> carried out an initial phenol-formaldehyde condensation in the presence of aqueous caustic potash and used phenols or urea in an acid medium as a binding agent for the uncombined aldehyde in the resinous product. Specifically, 1000 g. of phenol, 3000 g. of 30 per cent formaldehyde and about 50 cc. of 8 *N* potassium hydroxide are refluxed for a short time. Then, 18 cc. of 8 *N* lactic acid and about 58 cc. of a solution of phthalic anhydride in glycerol are added. The whole product is distilled *in vacuo*, 60 g. of urea being added during the distillation, and hardening being accomplished by heat treatment. Another species of synthetic resin is produced by fusing a non-hardening phenol-formaldehyde product, mixed with fillers, urea and paraformaldehyde.<sup>59</sup>

A phenolic gum (gum acceroides) may also be combined with urea and aldehydes, according to Novotny,<sup>60</sup> forming a thermosetting, resinous product. Fibrous materials (paper, cloth or wood flour) are incorporated in the mixture which is then sheeted and hardened. An addition of 10 per cent of dicyanodiamide (cal-

culated on the weight of the phenol) promotes the phenol-aldehyde reaction.<sup>41</sup> Phenol or its homologues will also form plastic masses when added to an aqueous solution of albumin in the presence of urea, ammonia and formaldehyde.<sup>42</sup> The mixture is congealed by heating or by acid substances, and hardening of the product is effected by the application of heat and pressure.

Phthalic anhydride was employed by Lougovoy<sup>43</sup> as a catalyst in forming phenol-urea-formaldehyde resins. A mixture composed of 120 parts of urea, 320 parts of 37-40 per cent formaldehyde, 94 parts of phenol and 20 parts of phthalic anhydride becomes milky on heating, and a resin, which cools to a hard, white mass insoluble in hot alcohol, acetone or benzene, separates. The resin is crushed, dried and molded at 120°C. under 2000 lb. pressure, giving products free from any reddish color. The milky solution formed in the early stages of the condensation can be diluted with an equal volume of alcohol and incorporated with fillers. The reaction can be carried out under anhydrous conditions, using paraform instead of aqueous formaldehyde. Hydrochloric or sulphuric acid can also be used in this process.<sup>44</sup> Using 100 parts of phenol, 25 parts of urea, 100 parts of aqueous formaldehyde and 2 parts of 50 per cent sulphuric acid and heating under reflux for 15 minutes, a slow-hardening resin is produced, that dissolves in hot acetone or in acetone-alcohol and benzene-methyl alcohol mixtures. The solutions dissolve nitrocellulose and are considered of value as coating compositions.

Spitzer<sup>45</sup> made thermohardening, light-resistant resins that dissolve in low-boiling solvents by causing formaldehyde to react with a phenol, urea and p-toluenesulphonamide.

Urea-formaldehyde-phenol condensation products were applied by Moss and Crutchfield<sup>46</sup> as an adhesive in the manufacture of laminated glass. The adhesive is prepared by refluxing 100 parts of phenol, 20 parts of urea and 150 parts of 40 per cent formaldehyde at 125°C. for 2 hours and vacuum distilling the resulting brown liquid until a soft resin remains. The product is soluble in alcohol, benzyl alcohol, ethyl lactate and acetone. Coating compositions composed of 10 parts of this resin, 4 parts of diethyl phthalate, 30 parts of acetone and 10 parts of alcohol are used to hold a celluloid sheet between layers of glass. Glass sheets are joined to a cellulose derivative by means of a phenol-urea reaction product in conjunction with other adhesives, including Canada balsam or euphorbium resin.<sup>47</sup>

Becherer<sup>48</sup> prepared a water-soluble product by treating a phenol-urea-formaldehyde resin with additional phenol and then at a raised temperature with a sulphonating agent. As an example, 80 parts of a resin (made by condensing 100 parts of phenol with 20 parts of urea and 120 parts of a 38 per cent formaldehyde solution at 85°C. in the presence of 2.5 parts of 40 per cent sulphuric acid) are stirred with 100 parts of phenol at 70° C. until a homogeneous solution is produced. Then, at a temperature of 40-110°C., 100 parts of sulphuric acid (sp. gr. 1.8354) are introduced and stirring is continued until a sample of the product is soluble in its own volume of water. After neutralizing the excess acid with sodium carbonate, the soluble resin can be salted out or separated by evaporation. These resins can be employed, according to Becherer, as tanning agents, mordants and wool reserving agents in the leather and textile industries.

Sulphonated phenols combined with thiourea-aldehyde or urea-aldehyde products were used in tanning by Somerville and Raterink.<sup>66</sup> These investigators found that urea derivatives act as retarding agents in the interaction of sulphonated phenols and aldehydes, thus controlling the reaction. The color of the condensed sulphonic acid is improved, and the synthetic tanning materials developed give white leather. The sulphonation of the phenol is performed by heating 94 lb. of phenol to 40°C., slowly adding 153 lb. of sulphuric acid (sp. gr. 1.8354) and heating at 95-100°C. for 2 hours. The solution is cooled, 70 lb. of water are added at 35°C., 15 lb. of thiourea stirred in during a period of 10 minutes, 63 lb. of 38 per cent formaldehyde added rapidly, and the temperature is then raised to

FIG. 114.—

into Top of Polymerizing  
Kettle.

*Courtesy Catalin Corp.*

80-85°C. for an hour. After cooling the solution, the free acid is neutralized with sodium hydroxide, and water is added until the weight is increased to 470 lb. The solution can then be employed in the tanning process. Tanning materials were prepared also by the condensation of sulphonated derivatives of phenols, cresols and naphthols with the reaction products from urea, formaldehyde and ammonium sulphide or ammonium thiocyanate.<sup>70</sup> The resulting acid products are partially neutralized by oxides or hydrates of heavy metals. According to Pollak,<sup>71</sup> formaldehyde or acetaldehyde may be condensed with a polyvalent phenol (resorcinol) together with urea and vegetable tanning materials at a temperature below 50°C. in the presence of an acid condensing agent. The final products are water-soluble tanning compounds. Condensation products of urea and formal-

dehyde added to a sulphonated phenol give alkali-soluble compositions used as tanning substances and also for weighting silk.<sup>72</sup>

Other investigators developed methods of alkaline condensation of urea and formaldehyde in the presence of substances (phenols, aniline and naphthylamine) capable of resin-formation with the aldehyde.<sup>73</sup> Kraus<sup>74</sup> formed a urea-formaldehyde resin in the presence of hexamethylenetetramine. This worker also suggested that a hexamethylenetetramine-phenol condensate be incorporated with a urea-formaldehyde resin. Starch, glue or gum arabic may be added to further modify the product.<sup>75</sup>

Salicylic acid was studied in connection with urea-aldehyde resins by Belfit.<sup>76</sup> The urea-formaldehyde resin is formed as an unhardened, liquid product, and to 81 cc. of this condensate are added 5 g. of salicylic acid, using 50 cc. of ethyl lactate as a solvent. The resulting lacquer necessarily contains some water, but the aqueous content should be kept as low as possible. Films from this coating composition (after hardening by a heat-treatment at 130-150°C.) are reported to be resistant to solvents and chemical reagents. If a small amount of castor oil is added to the lacquer, the resulting films are more pliable. Salicylic acid may be replaced by ammonium salicylate, acetylsalicylic acid, hydroxynaphthoic acids, gallic acids, metal salicylates or salicylamide. Arnot<sup>77</sup> also used salicylic acid, gallic acid and cresols for modifying urea resins. As early as 1904, Voswinkel and Lauch<sup>78</sup> produced for use in pharmacy a series of condensation products from tannin or its derivatives, urea and formaldehyde. Goldsmith<sup>79</sup> described a thermoplastic product that he obtained by subjecting gluten to the combined action of formaldehyde and  $\beta$ -naphthol. Voswinkel<sup>80</sup> used gallic acid for condensation with urea and formaldehyde, hydrochloric acid being the condensing agent.

#### MOLDING COMPOSITIONS WITH CASEIN

As early as 1910, Goldsmith<sup>81</sup> prepared a casein or gluten composition containing urea and formaldehyde. The function of the urea, however, was to serve as a softening or fluxing agent, unlike the present-day use of urea in urea-formaldehyde molding compositions. In this early work, urea was added (as one of a number of alternatives) to proteins (casein or gluten) and formaldehyde, forming a thermoplastic composition.

The incorporation of protein bodies such as casein, gelatine or glue with urea-formaldehyde resins is found to improve the molding properties of the resin, and was applied to this purpose by a number of workers. Redman<sup>82</sup> mixed 100 parts of casein, 100 parts of urea, 100 parts of paraformaldehyde, 50 parts of water, 40 parts of ethylene glycol and 13 parts of aqueous ammonia in a ball mill. The resin-forming reaction takes place on sheeting rolls to which the mixture is transferred, and the volatile components, including the reaction-water, are largely driven

off at this point. The almost anhydrous mixture obtained possesses good molding characteristics under standard conditions, yielding infusible articles little affected by neutral solvents. The surface appearance and water resistance of the molded products are enhanced by the addition of cellulose esters, and plasticizers (diethyl or dibutyl oxalates, tartrates or phthalates) improve the working qualities.

Landecker<sup>55</sup> found that a mixture of dry, powdered casein and urea added to water formed a glue, joints made with this composition being hardened by the inclusion of formaldehyde in the casein-urea solution. On adding excess of water to the casein-urea solution, an albuminous precipitate is formed. When this is filtered off, dried and molded with heat and pressure, a transparent, artificial horn is obtained. The molding pressure is materially lower than that required to mold casein alone. According to Ott, Schussler, Luther and Henek,<sup>56</sup> a mixture of 500 parts of casein and 500 parts of dimethylolurea, on being subjected to a pressure of 200 atmospheres for 3.5 hours at 100°C., gives a yellowish resinous mass. The casein is regarded by Schmidt<sup>55</sup> as a "carrier substance" in such a mixture. Thus, urea or its derivatives is condensed with formaldehyde and then dehydrated at 40-45°C. in the presence of carriers (casein, cellulose or its derivatives and certain natural or synthetic resins) in a kneading machine or between rollers. The final hot molding is similar to that used in processes already described.

A plasticizer obtained by condensing thiourea and formaldehyde was used by Bussard<sup>56</sup> to increase the fluidity of condensation products from ureides and formaldehyde.

#### RESINS FROM CYANAMIDE AND ALLIED SUBSTANCES

Cyanamide yields resins under conditions similar to those employed in the production of urea resins, and these resins show approximately similar properties. In acid solution, cyanamide hydrolyzes to urea,<sup>57</sup> and in the following an acid medium is sometimes employed.

Dicyanodiamide, which is capable of functioning as the urea derivative cyanoguanidine

was condensed by Wallasch<sup>58</sup> with formaldehyde in the presence of mineral acids, giving a viscous resin said to be of use as an adhesive.

Tomita<sup>59</sup> found that gelatinous products resulted on prolonged heating of a mixture of 300 cc. of a 3 per cent dicyanodiamide solution and 10 cc. of a 40 per cent formaldehyde solution. By acidifying the mixture with acetic acid or nitric acid, however, the gelatinous substance is formed at ordinary temperatures, but no such compound results when any other acid is used. After drying in air

at 25-30°C., the product becomes an elastic, glassy material, softening at 40°C., and it is used as an adhesive for wood, glass and porcelain.

Ripper<sup>90</sup> dissolved 100 parts of dicyanodiamide with 71 parts of urea in 200 parts by weight of a 40 per cent aqueous formaldehyde solution and refluxed the mixture for 2 hours. The water-clear reaction mixture is poured into water, and the resin separates as a flour-like powder which may be molded, after washing and drying, to give transparent articles. No catalysts or condensing agents are employed in this reaction. The condensation products of dicyanodiamide and formaldehyde with casein also furnish molding powders.<sup>91</sup> The casein is added during the condensation of the other reactants. In place of dicyanodiamide, urea or thiourea may be used. A dry mixture of dicyanodiamide, an albuminous material and a polymer of formaldehyde may be molded under heat and pressure.

The condensation of dicyanodiamide and formaldehyde may be carried out at a controlled  $p_H$  of 8-10 in the presence of a buffering mixture and sodium hydroxide, with an addition of metal salts (copper sulphate or zinc chloride).<sup>92</sup> This process yields a hydrophobic, heat-convertible resin. As an example of the manufacture of a resin of this type containing phenol,<sup>93</sup> 100 parts of dicyanodiamide and 112 parts of phenol are refluxed with 200 parts of formaldehyde for 2.5 hours, and the mixture is poured into cold water. The solid resin obtained is powdered, washed and dried, forming a molding powder with excellent flow characteristics. The products molded from this powder are slightly yellowish and transparent.

Variation in the proportion of formaldehyde used in the dicyanodiamide resins gives a wide modification of their properties.<sup>94</sup> Thus, 1 mol of dicyanodiamide condensed with 2 mols of formaldehyde for 3 hours at 60-80°C. yields a clear solution, from which a transparent resin, that can be mixed with urea or thiourea condensation products, is formed on evaporation. A molding powder, which flows easily and gives products that readily part from the mold, is prepared from 10 parts of dicyanodiamide and 10.7 parts of formaldehyde. Urea and thiourea serve as additional constituents in a large number of these resins. The interaction of 30 parts of dicyanodiamide, 58 parts of formalin and 12.6 parts of formic acid, after some hours heating, produces a transparent jelly, soluble in water. On heating the jelly for several hours at 80-90°C., a clear, brittle resin is obtained which swells like gelatin (with which it is miscible) in water and then dissolves. As the amount of formic acid employed decreases, the water-solubility of the product also lessens. A highly adhesive resin solution is obtained by mixing 84 parts of a urea-thiourea-formaldehyde condensation product, 16 parts of dicyanodiamide-formaldehyde resin and 1.3 parts of formic acid. The solution is evaporated on a water-bath until it contains about 20 per cent of water.

Sulphuric and hydrochloric acids give similar but less soluble jellies. The condensation of dicyanodiamide and formaldehyde in the presence of linoleic acid or stearic acid leads to the formation of soft, pale yellow resins that harden on exposure to air and can be used in the manufacture of varnishes. Ricinoleic acid also gives a clear soft resin, insoluble in water and benzene, but soluble in alcohol, hot ethylene glycol or a mixture of cyclohexanol and benzene. The resin is formed in these cases by heating the constituents together and then evaporating. The condensation products formed by using oleic, linoleic and ricinoleic acids are miscible with rubber and their use as plasticizers has been proposed. With oxalic acid, hard, white, brittle resins are obtained. Dicyanodiamide, in a quantity not exceeding 10 per cent of the amount of phenol, is used as a condensing agent in

making synthetic resins from phenols and aldehydes.<sup>96</sup> A formaldehyde-dicyanodiamide resin (30 parts) mixed with 70 parts of gelatin in aqueous solution can be used as an adhesive for glass sheets.<sup>96</sup> Schmidt<sup>97</sup> condensed formaldehyde and cyanamide in an aqueous solution containing a strong, inorganic acid by heating the mixture on a water-bath until the products separated in an amorphous condition. The condensation also may be carried out in a dilute, alkaline solution. A cyanamide solution prepared by treating crude calcium cyanamide with water may be used. John<sup>98</sup> described the condensation with formaldehyde of a filtered solution obtained by leaching, at 30-50°C., calcium cyanamide with water containing carbon dioxide. The leached solution contains cyanamide, dicyanodiamide, urea, calcium carbamate and guanidine. It is concentrated slightly by evaporation and then condensed in the presence of a little hydrochloric acid with formaldehyde, forming a gelatinous and finally horny mass. Calcium salts are removed, before or after condensation, by the addition of very dilute sulphuric or oxalic acid.

Thiodicyanodiamidine, already formed or prepared *in situ* by reacting cyanamide or dicyanodiamide with hydrogen sulphide, may be condensed with formaldehyde in alkaline solution.<sup>99</sup> The product is neutralized or acidified and heated, and a urea-formaldehyde condensation product may be added. After evaporating *in vacuo* to a thick syrup, the resin is mixed with fillers and molded. Rothera, Blythen and Gillespie<sup>100</sup> also prepared resins by the alkaline condensation of formaldehyde and thiodicyanodiamidine.

#### USE OF GUANIDINE

Guanidine, prepared from ammonium thiocyanate, forms resins with formaldehyde in the same way as urea.<sup>101</sup> Guanidine thiocyanate and guanidine carbonate give crystalline or amorphous resins that may be pressed. Guanidine derivatives and thiourea also give molding products with formaldehyde. The presence of water makes the resin opaque and liable to crack, but this difficulty is minimized by an addition of glycerol. Stine<sup>102</sup> described the preparation of synthetic resins from guanidine salts or derivatives and aqueous formaldehyde. The formula of guanidine carbonate, typical of the salts employed, is:

Benzaldehyde, acetaldehyde and other aldehydes may be employed instead of formaldehyde. As an example, 40 parts of 40 per cent formalin are refluxed with 15 parts of guanidine carbonate for 20 minutes. The resulting solution sets to a gel that forms a transparent resin on heating for 24 hours in a vacuum oven at 50°C. Further heating at 100°C. makes the product hard and infusible.

Guanidine was used in urea-formaldehyde condensations by Griffith.<sup>103</sup>

Guanidine salts make it possible to obtain colorless urea-formaldehyde resins over a wide pH range. In the method, the guanidine carbonate-urea mixture is refluxed with 2 mols of formaldehyde solution, evaporated and then dried, yielding a colorless, transparent resin.

A colorless, vitreous material is made by condensing urea and guanidine with formaldehyde in the presence of powdered zinc, trioxymethylene and hexamethylenetetramine. After boiling 1-3 hours the mass is filtered, freed from water at 25-40°C. and may be preserved as fluid or solidified.<sup>104</sup>

#### RESINS FROM ALDEHYDES AND URETHANS

The condensation of aqueous formaldehyde with urethan in the presence of hydrochloric acid forms methyleneurethan ( $\text{CH}_2=\text{N}-\text{COOC}_2\text{H}_5$ ) which gives trimeric methyleneurethan when boiled with dilute acetic acid.<sup>105</sup> If the oily reaction product is heated with acetic acid until all of the latter has been removed, resinous tetrameric methyleneurethan remains. A urethan such as methylol butyl urethan (2-5 per cent) is added to drying oil paints in order to obtain smooth, glossy finishes with white pigments (zinc oxide).<sup>106</sup> Water-insoluble urea derivatives or urethans with equal amounts of cellulose derivatives are used in the production of patterned films, sheets and coatings.<sup>107</sup> N-Methylolurethans are prepared by treating urethan with a polymer of formaldehyde in the presence of an alkaline condensing agent.<sup>108</sup> The methylol derivatives of urethan are stable at ordinary temperatures but yield formaldehyde when heated. A mixture of casein, methylol butyl urethan, water, butanol and acetone gives an interesting molded product when hot-pressed.<sup>109</sup> A mixture of urethan and urea will also condense with formaldehyde in an acid medium.<sup>110</sup> With an acid contact agent and at high temperatures, urea and urethan condense with aqueous formaldehyde to form products that may be hardened.<sup>111</sup>

#### MISCELLANEOUS MODIFICATIONS

Sulphur derivatives (thioaldehydes) of formaldehyde or benzaldehyde give soluble condensation products with urea.<sup>112</sup> The actual process entails pouring ammonium sulphide solution into urea (which dissolves) and adding formaldehyde solution. The liquid mixture sets to a crystalline mass on standing for 2-4 days in contact with aluminum. The products can be made insoluble (in water) by evaporation or by treatment with acids or alkalies. Conversely, the insoluble material yields substances dissolving in alcohol or water when treated with ammonium thiocyanate and additional formaldehyde. De Granville and Davion<sup>113</sup> added a sulphide

<sup>113</sup> J. de Granville and L. Davion, French P. 761,177 and 761,178, 1934; *Chem. Abs.*, 1934, 28, 4256.

during the condensation of urea and an excess of formaldehyde, in a medium brought to a  $p_H$  of 7 by means of potassium bitartrate, to assist fixation of sulphur on the resulting products. Colloidal sulphur, also, may be added to a condensation mixture with a  $p_H$  of 5. The mixture is then heated at 60°C. for 20 minutes and cooled quickly to 15°C. The resin is dried at 85°C. and ground, during which process p-toluenesulphamide and aluminum stearate are added. Armenault<sup>114</sup> produced plastic materials containing combined sulphur by treating urea-formaldehyde solutions with nascent hydrogen sulphide (formed *in situ* by the addition of a sulphide or polysulphide and an acid). Resins stated to possess elasticity and water-resistance can be prepared by condensing urea and formaldehyde in the presence of a compound containing the group -SS- (e.g., an alkali polysulphide or xanthate).<sup>115</sup>

Landecker<sup>116</sup> prepared a resin by dissolving 100 g. of urea in a solution containing 20 g. of ammonium sulphide and 250 cc. of commercial 40 per cent formaldehyde. The cloudiness of the solution disappears on warming, and a reaction which converts the liquid to a syrup and finally to a jelly takes place on boiling. The final product is a clear, highly refractive, solid mass which hardens on slow heating. A milky jelly, which can be molded into ivory-like articles, is obtained if sodium thiosulphate and formic acid are added to the urea-formaldehyde solution. The general properties of these resins somewhat resemble those of the natural albumins.

The problem of preserving urea-formaldehyde resins from deterioration due to liberation of formic acid was investigated by Lauter<sup>117</sup> who added an aromatic sulphonamide to the product. This type of compound is capable of taking up formic acid as it is formed. Thus, 706 g. of a 50 per cent, alcoholic solution of formaldehyde and 171 g. of p-toluenesulphonamide are heated to boiling, 180 g. of urea are added, and the mixture is refluxed until condensation is completed. The liquid product is mixed with fillers and molded.

Plastic products are obtained by condensing urea with formaldehyde and adding starch or flour in an amount equal to several times the weight of urea.<sup>118</sup> The addition can be made at any time during the operation. The products are hardened under pressure at 120-150°C. and are used for making buttons and similar articles. Natural or synthetic resins may be used as additional constituents and serve to increase the water-resistance. Organic colloids (e.g., agar-agar, proteins) may be present during the urea-formaldehyde condensation.<sup>119</sup> Gum tragacanth or starch were reported by Lionne<sup>120</sup> to retard the further condensation of urea-formaldehyde resins that were in the jelly stage. Proteins (e.g., casein) were added by Poulverel<sup>121</sup> during the resin-forming condensation of urea, phenol and formaldehyde in the preparation of plastic masses.

Seebach<sup>122</sup> prepared a hardenable product by treating urea with acetamide and

formaldehyde. The resin is dried, powdered, incorporated with filling materials and plasticizers and molded, being hardened by hot pressing. By kneading initial condensation products of the urea-formaldehyde type with substances capable of swelling (e.g., casein, cellulose or starch), Schmidt<sup>128</sup> obtained a dry composition that could be molded directly.

Printing color compositions were prepared by Paquin<sup>124</sup> by treating urea with aliphatic aldehyde-ammonia at 60-150°C. These compositions produce prints with enhanced depth of color when used with vat dyes such as those of the anthraquinone series. A resin can be obtained by condensing urea with formaldehyde in the presence of aryl ethers of glycols, according to Frick.<sup>126</sup> About 0.5 mol of the glycol derivative is used for each mol of urea. Water-soluble resins having emulsifying and wetting properties are prepared by heating aldols with urea at 110-120°C.<sup>125</sup> This product can be used to prepare wood and other surfaces for coating with cellulose lacquers.<sup>127</sup> Emulsifying agents are also obtained by condensing amino-alcohols with synthetic resin acids made by reacting natural resins with phenol-aldehyde and urea-aldehyde condensation products.<sup>128</sup>

By adding urea to fused chlorinated rubber and treating the mixture with formaldehyde in the presence of colophony or resin oils, Plauson<sup>129</sup> prepared water-resistant resins intended to be used as insulating materials. Alternatively, the urea may be added to fused chlorinated rubber, the mixture emulsified in water, and then treated with aqueous formaldehyde to give an emulsion.

The reaction between urea or its derivatives and solid polymerized formaldehyde can be effected in a melt of a solid hydrocarbon or a solid nitrated, chlorinated or hydrogenated substance.<sup>130</sup> Urea-formaldehyde condensation products give special resin compositions when mixed with casein, proteins, plastifying agents and glycol.<sup>131</sup> A product which forms elastic films and that can be used in aqueous solution as a coating for wood, textiles or metal is made by adding  $\beta$ -hydroxy-trimethylene sulphide to a urea-formaldehyde condensation product, during or after reaction.<sup>132</sup>

Spindler<sup>133</sup> prepared an organic glass by reacting carbon monoxide with ammonia at high pressures and at a temperature of 150-400°C. in the presence of a catalyst (iron, nickel, cobalt, copper or their compounds), forming urea and formaldehyde that combined in the usual manner. A thermohardening, colorless resin is prepared, according to Walter,<sup>134</sup> by condensing formaldehyde with p-sulphamino-benzamide (a by-product of saccharin manufacture).

Levi<sup>135</sup> found that ammonium N-disubstituted dithiocarbamates (NRR'-CS—NH<sub>2</sub>) react with glyoxal to yield solids that resinify more or less rapidly. Roll and Adams<sup>136</sup> described resins obtained from diphenyl carbodiimide. Auwers and Frese<sup>137</sup> reported that amorphous products with high melting points were formed by condensing 5-methyl-7-aminoindazol with urea. A number of resins occur also among the methylenediamide derivatives prepared by Bögemann and

<sup>137</sup> K. v. Auwers and E. Frese, *Ber.*, 1926, 59, 543.

Zaucker.<sup>138</sup> The polyamides of polycarboxylic acids (e.g., of adipic, suberic, diglycolic, hydrazine dicarboxylic or ethylenediamine-N,N'-dicarboxylic acid) can be condensed with formaldehyde (or related substances) to form resinous materials.<sup>139</sup> Christopher<sup>140</sup> prepared an adhesive by adding water to a powdered mixture of casein, biuret, cyanuric acid and formaldehyde. Cyanuric acid may be condensed with formaldehyde in water or organic solvents to give resinous products.<sup>141</sup>

Formaldehyde was used by Christopher and Beukelaer<sup>142</sup> to render glue or gelatin insoluble, and the product was then returned to a soluble form by the addition of urea. Lefebure<sup>143</sup> mixed water-soluble urea-formaldehyde condensation products, free from strong acids, with water-soluble salts of alginic acid and obtained compositions capable of forming stable solutions. Acetic acid or phenol are added to the mixture, and the products are used for paints, varnishes and for impregnating. Coloring matter incorporated with a urea-formaldehyde composition was used by the same investigator,<sup>144</sup> in the manufacture of decorated paper.

Substances having both waxy and resinous properties were prepared by Pungs and Stade<sup>145</sup> by combining crude or refined montan wax with urea-formaldehyde resins.

The reaction of urea with formaldehyde in the presence of zinc chloride gives a stable, syrupy, clear liquid suggested for use as an adhesive, coating or sizing. The method of preparation is as follows: 50 pounds of zinc chloride are dissolved in 275 pounds of 37 per cent formalin and 100 pounds of urea added.<sup>146</sup>

#### PRODUCTS WITH CELLULOSE DERIVATIVES

An aldehyde-urea condensation product may be added to an aqueous solution of a water-soluble alkyl cellulose (methyl cellulose), producing films or filaments on the removal of water.<sup>147</sup> The film formation is accelerated by heating or by exposure to ultraviolet light. A composition for ornamenting fabrics, yarns or paper, consisting of 15-60 per cent of a cellulose derivative with 40-85 per cent of the syrupy, intermediate condensation product of an aldehyde and urea or thiourea, was developed by Heynert and Lucius.<sup>148</sup> From 1 to 2 per cent of boric, lactic or phosphoric acid is added, together with mineral fillers, pigments and dyes. A urea-formaldehyde resin mixed with cellulose derivatives is used as a reinforcement coating for fragile glass or ceramic articles.<sup>149</sup>

An oxidation product of paraffin wax with nitric acid is esterified with butyl alcohol, and the resulting ester serves as a plasticizing and softening agent for lacquers, films and plastics containing cellulose derivatives, urea-aldehyde reaction products and other resins.<sup>150</sup>

## Chapter 33

### Amine-Aldehyde Resins

The general reaction between formaldehyde and primary and secondary amines entails the formation of methylolamines, which are unstable and lose water, forming higher products derived from methyleneamines.

Even ammonia at low temperatures forms trimethylolamine, which changes readily to hexamethylenetetramine. Under the influence of an alumina catalyst, however, pyridine was the main product of the interaction of ammonia with mixtures of acetaldehyde and acetaldehyde.<sup>1</sup>

The condensation of aniline and formaldehyde follows the general reaction, anhydroformaldehydeaniline,  $(\text{C}_6\text{H}_5\text{N=CH}_2)_x$ , being formed. This is a six-membered ring compound of the structure

A higher polymer of the same empirical formula,  $\text{C}_7\text{H}_7\text{N}$ , is formed at the same time. In the presence of condensing agents, however, it is probable that formaldehyde reacts with the aromatic nucleus as well. For example, by using a mixture of concentrated sulphuric acid and acetic acid, or preferably 10 per cent sulphuric acid, Kroneberg<sup>2</sup> obtained from o-toluidine and formaldehyde a polymeric compound, to which he assigned the questionable structures

<sup>1</sup> A. E. Chichibabin and M. P. Oparina, *J. Russ. Phys.-Chem. Soc.*, 1924, 54, 601; *J.C.S.*, 1924, 126(1), 313. See also A. E. Chichibabin, *J. prakt. Chem.*, 1924, 107, 122; *Chem. Abs.*, 1924, 18, 1666.

<sup>2</sup> A. M. Nastyukov and P. M. Kroneberg, *J. Russ. Phys.-Chem. Soc.*, 1912, 44, 1200; *Chem. Abs.*, 1913, 7, 933. P. M. Kroneberg, *J. Russ. Phys.-Chem. Soc.*, 1916, 48, 305; *Chem. Abs.*, 1917, 11, 532.

When the product was distilled, some diaminoditolylmethane, reminiscent of certain

of the phenol-formaldehyde intermediates, was obtained. This does not show whether the diphenylmethane structure is actually present in the original product, or is formed during the distillation. The nuclear combination of formaldehyde is probable, since it is known that dimethylaniline and formaldehyde in the presence of hydrochloric acid form p,p'-tetramethyldiaminodiphenylmethane,

Researches, on the condensation of aromatic amines with formaldehyde in media containing acid, by Eisner and Wagner<sup>a</sup> have led to the isolation of several products of the amine-aldehyde reaction. The interaction of formaldehyde and p-toluidine was studied under conditions insuring a minimum formation of resinous higher-condensation products. The condensation was effected at or below room temperature in the presence of an excess of dilute hydrochloric acid, using slightly more than 1 equivalent of a 37 per cent formaldehyde solution. Final separation of the resultants of the reaction yielded a small amount of resinous material, a base ( $C_{24}H_{27}ON_3$ ) melting at 140°C., a base ( $C_{17}H_{18}N_2$ ) melting at 135°C and an additional base ( $C_{16}H_{18}N_2$ ) melting at 162.5°C. which was identified as 3-p-tolyl-6-methyl-3,4-dihydroquinazoline. A steam-volatile oil obtained during the course of the experiment was found to contain p-toluidine, methyl-p-toluidine and dimethyl-p-toluidine which latter compound was unexpected. The effect of increasing amounts of formaldehyde on the composition of this steam-volatile liquid was studied in order to explain the formation of the dimethyl-p-toluidine, and the results are shown in Table 33.

TABLE 33.—*Methylation of p-Toluidine Hydrochloride by Formaldehyde.*

Composition of steam-volatile products

Molar Ratio $CH_2O:C_7H_7N$	p-Toluidine %	Methyl-p- toluidine %	Dimethyl-p- toluidine %	Amine-H replaced by $CH_3$ %
1 0	68	27	0	2 3
1 5	3	20	77	7.7
2 0	0	0	100	6 7
2 5	0	0	100	8 5
5 0	0	0	100	9 1

The effect of increase in the proportion of formaldehyde was not so much an increase in the number of p-toluidine molecules methylated as an increase in the thoroughness of methylation of the molecules affected.

Wagner<sup>a</sup> heated aromatic amines (n-propylaniline, n-butaniline, isoamylaniline, o-toluidine and m-toluidine) and a half equivalent of formaldehyde in acid solution. The resins obtained were found in some cases to be stable bases distillable *in vacuo*, but the quantities obtained were too small to permit further study. In the aniline reaction, a condensation product boiling at 329-334°C. (at 1-2 mm. pressure) was formed, and its nitrogen content (13.75 per cent) and molecular weight (351) indicated a mixture of trinuclear and tetranuclear bases (e.g.,  $C_{30}H_{31}N_3$  and  $C_{27}H_{28}N_4$ ).

<sup>a</sup> A. Eisner and E. C. Wagner, *J.A.C.S.*, 1934, 56, 1938.

<sup>a</sup> E. C. Wagner, *J.A.C.S.*, 1934, 56, 1944.

Benzidine reacts with terephthalaldehyde and isophthalaldehyde to form high-melting, insoluble substances. Adams, Bullock and Wilson<sup>6</sup> assigned the following structures to these products.

Mann<sup>8a</sup> found that aniline and acraldehyde reacted at 0°C. forming a resinous product according to the equation

With p-toluidine an analogous compound of the formula  $\text{C}_{20}\text{H}_{24}\text{ON}_2$  was obtained. The aniline derivative was a white amorphous precipitate, which rapidly developed a deep red color owing to oxidation. Littman and Brode<sup>9</sup> represented the condensation of secondary amines with benzaldehyde by the following equation

A further example of the isolation of definite compounds from amine-aldehyde condensations is furnished by the reaction between benzidine and formaldehyde, studied by Kondo and Ishida.<sup>7</sup> They found that dihydroxymethylenebenzidine was obtained as a grayish-white amorphous powder, sintering at 260° C. and melting at 271-272°C., by adding 30 cc. of 35 per cent formaldehyde solution to 10 grams of benzidine dissolved in 200 cc. of absolute alcohol.

Schiff bases are condensation products of aromatic aldehydes and primary amines. Wagner<sup>8</sup> has carried out reduction studies on Schiff's bases of the simple type  $\text{RCH}=\text{NR}'$  (azomethines) to gain evidence of their structure. Methylene-p-aminophenol was prepared<sup>9</sup> in alkaline or neutral solution by the condensation of p-aminophenol and formaldehyde. Made in the presence of alkali, this compound is a white, amorphous powder that darkens and becomes resinous in air. Cryoscopic determinations of the molecular weight of methylene-p-aminophenol suggest that it can exist wholly or largely monomeric, but the degree of its polymerization is indefinite. While investigating the catalytic hydrogenation of cyano derivatives, Rupe and Pieper<sup>10</sup> reduced ethyl benzylideneacyanoacetate obtaining two products, the half aldehyde of benzylmalonic acid and an amino acid ( $\alpha$ -benzyl- $\beta$ -amino-propionic acid). The two products condense together to form a Schiff base, which is obtained as a resin and can be separated into its components with mineral acid. Miller and Wagner<sup>11</sup> found that the lower normal aliphatic aldehydes other than formaldehyde when condensed with aniline gave the di-imine, the simple azomethine,  $\text{C}_6\text{H}_5\text{N}=\text{CHR}$ , changing to the dimeric molecule, repre-

<sup>10</sup> H. Rupe and B. Pieper, *Helv. Chim. Acta*, 1929, 12, 637; *Chem. Abs.*, 1929, 23, 4463.

<sup>11</sup> J. G. Miller and E. C. Wagner, *J.A.C.S.*, 1932, 54, 3693. The behavior of isobutyraldehyde is referred to by E. Friedling and G. Mossler (*Monatsh.*, 1901, 22, 460; *J.C.S.*, 1901, 80 (1), 641) and that of isovaleraldehyde by A. Eibner and G. Purucker (*Ber.*, 1900, 33, 3658). Hexahydrobenzaldehyde reacts with ammonia to form the imine almost exclusively which then polymerizes to give a stable compound,  $(\text{C}_6\text{H}_{11}\text{CH}=\text{NH})_x$ . (C. F. Winans and H. Adkins, *J.A.C.S.*, 1933, 55, 2058.)

sented, e.g., by the compound,  $C_6H_5NH-CH(CH_3)-CH_2CH=N-C_6H_5$ , due to an aldol-like condensation. These products were oils. By condensing pure aniline and pure acetaldehyde, with chilling, ethylidene-dianiline

a white crystalline solid, was formed. In their research on the character of nitrogen-containing synthetic resins (e.g., Schultz's bases), Eibner and Koch<sup>12</sup> added 18 g. of acetaldehyde in 180 cc of water to a solution of aniline hydrochloride (64 g.) in water (640 g.) at 0°C. If the reaction mixture is neutralized at once, 10 per cent of a resin (which melts at 126°C. when crystallized from ether and is identical with Eckstein's base) is precipitated. If, however, the mixture is allowed to stand for 4 weeks without neutralization, an alcohol-soluble resin (Schultz's base) melting at 175-185°C. is formed. Schultz's base proved to be a mixture of two compounds. Petroleum ether precipitates from an ether solution a resin melting at 175-185°C. and ether precipitates from a benzene solution a resin which sinters at 250°C. Schultz's bases are the result of a polymerization of Eckstein's base with the removal of the aniline group adjacent to the double bond. In the paint industry Schultz's bases are of little value because they swell, discolor, are brittle and prevent hardening of the paint film.

Levi<sup>13</sup> has carried out an extensive investigation of the condensation reaction of aminophenols and aldehydes with a view to using the products in the rubber industry. A number of new substances were described, some being crystalline and others amorphous, though no tests of their effect on rubber are recorded. The reaction was carried out in water solution, with the materials suspended in water, if insoluble, or between the aldehyde and a hydrochloric acid salt of the aminophenol in the presence of ammonium acetate. Glazer and Frisch<sup>14</sup> have studied the condensation products from acid amides and aldehydes either by melting the reactants together or by allowing them to react in alcoholic solution in the presence of hydrochloric acid. In this case, also, definite crystalline products of known composition were obtained.

Tar and resin formation has been recorded in other reactions, however. In condensing diethylaniline with phosphorus trichloride, Bourneuf<sup>15</sup> obtained a resinous product, although a similar treatment of dimethylaniline gave pure compounds. The sodium compound of N-benzylideneglycylglycine resinifies quickly on exposure to air, becoming red in color.<sup>16</sup> A yellow amorphous mass was secured by Reissert and Händler<sup>17</sup> when an ice-cold solution of isatin, which was acid to Congo red, was treated with formaldehyde and an excess of mineral acid. Klason<sup>18</sup> observed the formation of tars in the reaction between paraldehyde and  $\beta$ -naphthylamine hydrochloride. Pyman<sup>19</sup> reported much resin formation in the condensation of glyoxaline with formaldehyde. The reaction was effected at 125-135°C. in a sealed tube with 40 per cent formaldehyde. On heating together aniline and  $\beta$ -chlorobutaldehyde diethylacetal in a sealed tube at 220°C. for 5 hours, a dark brown oil was formed, which on fractionation gave a large amount

<sup>18</sup> P. Klason, *Ber.*, 1925, 58, 1763; *Chem. Abs.*, 1926, 20, 399. The tar remaining after the distillation of  $\alpha$ -naphthylamine in *vacuo* was analyzed by V. Lenkhold and E. Ostroumov (*J. Chem. Ind. (Russia)*, 1929, 6, 216; *Chem. Abs.*, 1930, 24, 3009). Iron oxides, lubricating oil, 6 per cent of  $C_{10}H_7NH_2$ , and traces of  $\alpha$ - and  $\beta$ -naphthol were found.

<sup>19</sup> F. L. Pyman, *J.S.C.I.*, 1927, 46, 1151.

of tar.<sup>30</sup> Gray<sup>31</sup> found that only tarry products were produced when d-glutamic acid and diphenylamine reacted at 240°C.; at lower temperatures, 1,2-pyrrolidone-5-carboxyanilide formed. Knoevenagel<sup>32</sup> has reported the resinification of the dimer of acetone-anil,

In a study of Döbner's reaction<sup>33</sup> between aromatic aldehydes, amines and pyruvic acid, Carrara<sup>34</sup> obtained high yields of resins and low yields of quinoline-γ-carboxylic acids. For instance, by adding dropwise 40 parts of pyruvic acid to a boiling mixture of aniline (67 parts) and benzaldehyde (76 parts) in an excess of ethyl alcohol and refluxing for 5 hours, 100 parts of a viscous, brown resin are given. Levine and Wehmhoff<sup>35</sup> have described a condensation product, deep red in color, of o-aminophenol and oxalic acid. This substance melts at 271-272°C. and decomposes when heated a few degrees above its melting point giving carbon dioxide and a tarry substance which could not be purified. Increased heating entirely decomposes the red product into carbon dioxide, water, o-aminophenol and an unidentified substance melting above 300°C. β-Ethoxy-acrolein-acetal was reported by König and Seifert<sup>36</sup> to give a soft resin when reacted with dimethylaniline in the presence of zinc chloride.

Electrolytic reduction of o-, m-, and p-chlorobenzylidene anilines yields the corresponding chlorobenzyl anilines, together with a resin. The amount of resin formed diminishes as the substituent group advances towards the center of the molecule. Thus I yields more resin than II.

Electrolytic reduction of the tolylidene toluidines also yields resins. Less resin is formed in this case when the substituting groups are evenly distributed in the two benzene nuclei.<sup>37</sup>

Bytebier,<sup>38</sup> in preparing diaminodiphenylmethane from aniline and formaldehyde, observed that under certain conditions synthetic resins, similar in appearance to rosin, were formed. These substances were soluble in the organic solvents used in the paint industry, and also in warm acid solutions, showing them to be basic in character. A resin of this sort was obtained, e.g., on pouring 1 molecular proportion of formaldehyde at 0-5°C. into a mixture of 1.13 mols of hydrochloric acid, and 2.25 mols of aniline. After 1 hour the mixture is heated to 90-95°C. and maintained at this temperature for 10 hours, the resin being precipitated on making the solution alkaline with caustic soda.

In the case of the reaction between aldehydes and amines the nature of the product is controlled very largely by the conditions. The character of the products formed in the reaction of formaldehyde with diphenylamine depends on the relative proportions of the reactants.<sup>39</sup> An excess of diphenylamine favors the

formation of a definite compound,  $\text{CH}_2(\text{C}_6\text{H}_4\text{NHC}_6\text{H}_5)_n$ , whereas an excess or even an equimolecular proportion of formaldehyde results in the formation of resins. It is possible in some cases to isolate definite compounds, but in other circumstances only the ill-defined resin is formed. It can be stated quite generally that the resinous substances are either higher polymers, or represent a greater degree of condensation than that in the identifiable derivatives

Resin formation in these reactions is favored by (1) higher temperature and greater duration of reaction; (2) excess of the aldehyde and (3) the presence of a catalyst, especially an acid. In the following account of some of the chief amine-aldehyde resins little reference is made to the probable composition. It will be understood that in practically every case they represent the product of a more or less complex condensation reaction of the type already outlined.

#### RESINS FROM ANILINE AND FORMALDEHYDE

The production of resins of this type<sup>30</sup> has been developed largely during the last ten years. An acid is used in most cases as a condensing agent, a feature which offers a parallel with the production of resins from aldehydes and urea.<sup>31</sup>

Böhler<sup>32</sup> prepared a resin by heating anhydroformaldehydeaniline to a temperature of 130-140°C. for 10 to 12 hours. A dense cloud of white vapors is given off during the reaction. The presence of aniline during the distillation is desirable as it appears to facilitate the reaction and to improve the solubility of the resin in benzene or alcohol. Slight amounts of acids or alkalis may be added to the reaction mixture. This synthetic resin is said to have the property of increasing the solubility of difficultly-soluble natural or synthetic resins and to improve their qualities otherwise. Soane<sup>33</sup> obtained a resilient composition for printers' rollers by treating a water-containing mixture of glue and glycerol with aniline-formaldehyde condensation products. Berend<sup>34</sup> prepared these substances by dissolving glue in equal parts of phenol and glycerol and adding shellac, dissolved in aniline and homogenized by heat with paraformaldehyde. The temperature of the mixture is raised to 70°C. and glycerol-formaldehyde or additional paraformaldehyde is added. The tough mass which results is molded before solidifying. In the course of preparation of anhydroformaldehydeaniline from aniline and formaldehyde Eberhardt and Welter<sup>35</sup> obtained some polymerized anhydro compounds and resinous bodies.

Since 1928, investigators have introduced a number of adaptations and modifications of the general method of condensing aromatic amines with formaldehyde. One molecular proportion of aniline may be condensed with 1 mol of formaldehyde in the presence of at least 0.25 of the equivalent amount of hydrochloric acid, calculated on the basis of the amine. The resinous material precipitates as soon as the acid is neutralized. After removal of the acid, the resin (m. p., 180-200°C.) is dried, pulverized and then hardened with more formaldehyde.<sup>36</sup> The density of the porous product of such a condensation is increased by heat and pressure, e.g., by heating for about 1 hour at 150°C. and 100 atmospheres pres-

sure.<sup>37</sup> The hydrochloric acid is eliminated by treatment with a 3 per cent sodium hydroxide solution. The heat and pressure treatment increases the specific gravity of the resin from 0.6 to about 1.0<sup>38</sup> and improves the working properties and insulating capacity of the product. The compression of this condensation product may also be carried out in the presence of fluxes, such as a fusible non-hardening phenol-formaldehyde condensation product.<sup>39</sup> A filling material (sawdust) may be impregnated with the amine-aldehyde condensation product before eliminating the acid. The condensation products are afterwards precipitated in the filling material by adding an agent to neutralize the acid (an acid binding agent), and the final product is washed, dried and hot-molded, hardening agents being added if required.<sup>40</sup> The following example illustrates the use of these bodies in conjunction with a filler.<sup>41</sup> Aniline is condensed with formaldehyde in presence of hydrochloric acid. After being kept at 30°C. for half an hour, the resin is precipitated by being run into sodium hydroxide solution, and is then washed free from electrolytes. A fibrous or powdery filler (wood flour, asbestos or cotton) is mixed with the moist condensation product (before or after washing) and the mixture is eventually hot-molded. Aldehydic hardening agents, fluxing agents or coloring materials may be incorporated before molding.<sup>42</sup> Resins similarly prepared may be applied to supports and then subjected to heat and pressure.<sup>43</sup> A resin to which fillers or plasticizing agents may be added is formed by the reaction of a primary aromatic amine with more than 2 mols of formaldehyde and a large amount of strong mineral acid, at a high temperature.<sup>44</sup> The product is washed, dried and compressed by heating under pressure. Using filling materials (e.g., sulphite pulp, leather chips or cellulose) it is possible to make paper-like material (cardboard) and imitation leather by this process.<sup>45</sup> Insulators of the condenser type, for the terminals of high-tension transformers, are obtained by molding and compressing together an assemblage of metal sheets coated with the product of the acid condensation of aniline and formaldehyde.<sup>46</sup>

The infusible (hardened) and insoluble condensation products obtained from an aromatic amine and more than 1 molecular proportion of an aldehyde may be converted into fusible and soluble products by heating them with a fusible aldehyde condensation product of phenol, or with a non-aldehydic fusible synthetic resin as that from glycerol-phthalic acid.<sup>47</sup> As an example, aniline is treated with more than 1 mol of formaldehyde in the presence of hydrochloric acid, and a

solution of a phenol-formaldehyde resin is added. The mixture is then neutralized with sodium carbonate, heated and the resin filtered off. The added substance here plays the part of a fluxing agent. Conversely, the fusible condensation products prepared by the reaction of formaldehyde and primary amines in the presence of nearly equivalent quantities of acid may be made infusible by the action of fresh amounts of aldehydes at temperatures less than 140°C. The final hardening is done at higher temperatures under pressure.<sup>48</sup> The condensation product from amines and aldehydes has been suggested for making joints tight against liquids, vapors and gases.<sup>49</sup>

By dissolving the condensation product from an aromatic amine and formaldehyde, in presence of almost an equivalent quantity of acid, together with aldehydes or agents liberating aldehydes in the common solvents, solutions are obtained which are used for the production of insoluble coatings stable to heat, and which have a high mechanical and chemical resistance.<sup>50</sup> Chlorohydrins are employed as solvents for the infusible condensation products. Additions of softening agents, pigments, cellulose derivatives, fillers, rubber, resins and diluents may be made to the solutions, which are proposed for use as lacquers.<sup>51</sup> Glycol chlorohydrin or epichlorohydrin, mixed with swelling agents including cyclohexanone, ethyl lactate and chloroform, are generally used, solution being accelerated by heating.<sup>52</sup> Light<sup>53</sup> condensed equimolecular proportions of formaldehyde and a primary aromatic amine in the presence of an acid for 5 minutes at 70°C. and, subsequently, several minutes at 90°C. Further heat-treatment converts the resinous residue into hard, transparent, pale yellow to orange resins, which may be made opaque by boiling with water.

An oil-modified resin is obtained by heating a drying oil (e.g., tung oil) with aniline and treating with anhydroformaldehydeaniline. The product is rendered thermosetting by reaction with formaldehyde.<sup>54</sup>

#### IMPREGNATION OF PULP WITH ANILINE-FORMALDEHYDE RESINS

Kienle and Scheiber<sup>54</sup> carried out the condensation of an aromatic amine (aniline, 1 mol) with an aldehyde (formaldehyde, 1 mol) in hydrochloric acid solution at 40°C. and added a fibrous pulp, with or without a filling material, to the clear acid liquid. After stirring for 1 hour to saturate the pulp, the mixture is diluted with water, and an alkali (lime) added to neutralize the acid and to precipitate the resin which is flocculated at 60°C. The stock is beaten and sheets formed from the stock on a paper-making machine, several such sheets being superimposed. Molding of the product is carried out at 150°C. and at a pressure greater than 1000 lb. per square inch. The flocculated product may be diluted to a consistency of about 1 per cent and formed into sheets, which are dried, calendered and heated under pressure. The following example gives some further details

of the process employed.<sup>55</sup> The initial condensation is carried out with a mixture of 15,000 lb. of water, 920 lb. of aniline, 990 lb. of 36 per cent hydrochloric acid and 912 lb. of 38.8 per cent formaldehyde, the ordinary paper mill beater serving as a reaction chamber. The reaction temperature is not allowed to rise above 40°C., and condensation is complete in an hour. The pulp is now added, a quantity of 100 lb., calculated on a dry weight basis, being the usual amount. After the pulp is saturated, the mixture is diluted with 10,000 lb. of water, and 420 lb. of lime, preferably as milk of lime, are added to neutralize the acid and precipitate the resin. The temperature is raised to 60°C., and the material is beaten to bring about an attachment of the resin flocculates to the fibers,<sup>56</sup> a step which may take from 2 to 40 hours, depending on the conditions and materials used. After heating, the stock is diluted to about 1 per cent and delivered into a paper-making machine, and the sheet pulp is dried, calendered and pressed. (See Fig. 115.) A resin prepared in a similar manner may be used on and around the interlocked fibers of a wet paper pulp which is built up in layers to form a

laminated product. The mass is dried and molded under heat and pressure.<sup>57</sup> The molded material is an inert, infusible body of great mechanical strength, and with good insulating qualities. It is used in the manufacture of various articles such as laminated products, insulating tapes, gears, slot insulating materials, transformer spacers and refrigerator strips. Laminated tubes are prepared by impregnating paper with fusible, non-hardening resins of the anhydroaminobenzyl alcohol type (e.g., from formaldehyde and aniline hydrochloride) and making up in a tube-rolling machine.<sup>58</sup> This type of resin is also used as a binder in making lamellar masses.<sup>59</sup> The layers are impregnated with the resin and assembled by the action of heat and pressure. The anhydro-p-aminobenzyl alcohol binding agent is also mixed with fibers, and various articles are made from it by hot-pressing.<sup>60</sup> Kienle considers that the use of a strong alkali (caustic soda)

<sup>55</sup> R. H. Kienle and W. J. Scheiber, U. S. P. 1,812,749, June 30, 1931, to General Electric Co.; *Chem. Abs.*, 1931, 25, 5027. to precipitate the resin leads to a product which does not lend itself readily to molding.<sup>61</sup> The product with sodium hydroxide lacks flow, which is a serious drawback when molding with fillers. To overcome this difficulty precipitation is carried out with calcium, barium, or magnesium hydroxide. An added advantage of the use of these agents is the production of more soluble salts on neutralization. Amine-aldehyde resins of greater fluidity are also prepared by replacing aniline with toluidines, diphenylamines, naphthylamines or benzidines.<sup>62</sup>

#### OTHER APPLICATIONS OF ANILINE-FORMALDEHYDE RESINS

Vacher<sup>63</sup> developed a method of preparing a resin of the type under consideration by heating together 100 parts of aniline and 90 parts of 40 per cent aqueous formaldehyde with 25 parts of a phenol (especially cresol) as a catalyst. Unreacted material is distilled off under reduced pressure (500 mm.) and the product on heating to 170°C. is converted into an infusible, insoluble resin. Molding may be combined with this heat treatment. Before the final treatment, the product melts between 50-80°C. to a liquid with approximately the viscosity of water, and it may be used in this state for impregnating, or, dissolved in an organic solvent, may be employed as a varnish. Vacher also utilizes acids, bases and salts as catalysts in addition to phenols. The final hardening of the resins may be carried out by heating in the presence of a hardening agent (hexamethylenetetramine).<sup>64</sup>

Anhydroformaldehyde compounds given by the condensation of salts of aromatic amines with resin acids or fatty acids of high molecular weight and formaldehyde were prepared by Berend<sup>65</sup> and may be used as substitutes for camphor and as solid solvents for nitrocellulose, in the manufacture of varnishes. For example, 80 g. of oleic acid are dissolved in 60 g. of aniline and warmed on a water-bath with 20 g. of paraformaldehyde until reaction ceases. An amorphous, yellowish-white mass, melting at 50°C., is obtained. The excess aniline is removed by boiling the product with water.

The use of aromatic amines other than aniline is recommended by Schlingman,<sup>66</sup> as giving an easily moldable resin. Benzidine and diphenylamine are mentioned in this connection, condensation with the aldehyde being carried out in acid solution and the condensation product precipitated with a base. The use of amines having a larger space arrangement in the molecule than aniline results in the formation of resinous compositions with increased flexibility and plasticity.

Anhydrous aldehydes or their solid polymers (2 mols), and aromatic amines (1 mol), may be condensed in the presence of a polybasic organic acid, particularly phthalic acid, in a solvent (benzene, alcohol or aniline).<sup>67</sup> The condensation of anhydrous formaldehyde and aniline may be effected in ethyl alcohol solution in the presence of phthalic acid and a contact substance such as stannic chloride.<sup>68</sup> The reaction product is subsequently hardened. The softening point

of these aniline-formaldehyde resins is raised by restricting the amount of the phthalic acid to not more than 0.04 equivalent (relative to the amine) and by a subsequent heat treatment.<sup>69</sup> Molding substances may be manufactured in a single condensation step in the absence of solvents on heated mill rolls.<sup>70</sup> Wood flour, paraformaldehyde, aniline, phthalic acid and coloring matter are processed in a rubber mill at 120-140°C. producing compact sheets which may be further worked. Similarly,  $\alpha$ - or  $\beta$ -naphthylamine, crotonaldehyde, benzoic acid and coloring matter can be reacted and the product powdered for molding. Condensation products of this type are also applied in the utilization of waste rubber. A molding material is produced by mixing rubber waste or dust with a binding agent, consisting of an aldehyde-amine condensation product, which softens within the temperature range at which the rubber becomes soft or plastic.<sup>71</sup> Paraformaldehyde-amine condensation products are also utilized as adhesives, layers of material being bonded by the resin, which is then hardened by heating to 150°C. for 30 seconds.<sup>72</sup> Layers of a fibrous substance (paper, fabric) are processed in this manner to give laminated material for electrical insulation.<sup>73</sup> Haller and Kappeler<sup>74</sup> carried out the condensation below 100°C. between an aromatic amine (aniline, toluidine) and formaldehyde in the presence of hydrochloric acid, acetic acid or potassium bisulphate. The orange-red product is washed and then treated with alkali (a solution of sodium hydroxide, ammonia, milk of lime, sodium carbonate or alkali sulphide). A whitish mass resembling bone or horn is precipitated. Alternatively, the base and formaldehyde may be condensed first in an alkaline medium, and the product condensed with more formaldehyde in an acid medium, followed by washing and treatment with alkali. Fillers, softeners and pigments may be added. This process was further modified by treating the amine-aldehyde condensation product with an organic base, a neutral or acid salt or an organic acid (e.g., with methylamine, pyridine, aqueous ammonium chloride or acetic acid).<sup>75</sup> The aldehyde-amine reaction is continued until a jelly forms; then the supplemental amine, for example, is added, and the mass washed and dried.<sup>76</sup> The products have a wood-like, bony or horny appearance and are used as substitutes for bone and horn or as insulating materials. The product is further improved by adding salts soluble in water or alcohol to the amine. Thus, sodium chloride, ammonium chloride or ammonium nitrate is added to the aniline, hydrochloric acid and water before adding the formaldehyde.<sup>77</sup>

Acid solutions of the condensation products of aromatic amines and aldehydes in the form of gels and containing fillers (sawdust or mica) are pulverized during formation and the acid is separated.<sup>78</sup> After washing and drying, the material may

be compressed into desired shapes. Molding powders, also, may be prepared from a mixture of a filling material and an acid solution of an aromatic amine and an aldehyde, which has a tendency to gelatinize. This is accomplished by disintegrating the gel during or after its formation but before solidification.<sup>79</sup> Thus, a solution of aniline hydrochloride in water is treated with formaldehyde and wood flour stirred in; the product is neutralized with sodium hydroxide, washed and dried. Amine-aldehyde resins have some use as coatings. A resin of low softening temperature with or without an added filling (quartz, kaolin) or softening material is selected and sprayed on the article to be coated.<sup>80</sup> By dissolving aniline-

formaldehyde condensation products in a chlorohydrin (glycolchlorohydrin or glyceroldichlorohydrin), Gams and Frey<sup>81</sup> obtained a solution of use in varnishes and lacquers.

Amine-aldehyde reaction products give useful resins with phenols. Achtmeyer<sup>82</sup> produced non-inflammable friction compositions by the interaction of phenolic bodies with methylenediphenyldiamine,  $\text{CH}_2(\text{NHC}_6\text{H}_5)_2$ . This compound is prepared by allowing aniline, formaldehyde and potassium hydroxide to react in alcoholic solution at  $100^\circ\text{C}$ .<sup>83</sup> Specifically, the phenol friction-material is obtained by adding 100 parts of phenol to 75-100 parts of methylenediphenyldiamine in a steam-jacketed, open vessel provided with a stirrer. The mass is heated to boiling and heated further to remove water. This is treated with paraformaldehyde (7 to 10 per cent) and given a further heat treatment in order to convert the

thin liquid product into a hard and insoluble resin. Dissolved in a high-boiling solvent (amyl acetate) before the final heat treatment, it may be used to impregnate porous and cellular materials. These compositions are baked at 300-400°C. and may be used as brake linings.

Bender<sup>88</sup> prepared a fusible, potentially reactive resin by reacting anhydroformaldehydeaniline with phenol. A fusible resin, soluble in organic solvents, was developed by Seebach<sup>84</sup> from a phenol, formaldehyde and aniline, toluidine or  $\alpha$ - or  $\beta$ -naphthylamine. More than 0.5 mol of phenol is used per mol of amine. Salts or derivatives (including, e.g., anthranilic acid, 1-naphthylamine-5-sulphonic acid) of amines are also employed in the process. The resins formed are characterized by containing a constant proportion of nitrogen.

Wayne<sup>85</sup> resolved petroleum emulsions by treating with a water-soluble condensation product such as that formed from sulphonated aniline and formaldehyde. Amine-formaldehyde resins were used by Siedler and Moeller<sup>86</sup> to prevent premature crystallization of supersaturated solutions of thiocarbanilide.

Burke<sup>87</sup> has used the reaction between amines and aldehydes to purify aldehyde-contaminated lower aliphatic alcohols. For example aniline was added to ethyl alcohol containing an aldehyde. The reaction product of amine and aldehyde was separated from the alcohol by distillation.

#### CONDENSATION OF OTHER AMINES WITH FORMALDEHYDE

Reaction between an amine (o-toluidine, aniline,  $\alpha$ - or  $\beta$ -naphthylamine) and at least one molecular proportion of formaldehyde may be brought about in the presence of water-soluble organic solvents for the amine, volatile by-products being distilled off *in vacuo* from the reaction product.<sup>88</sup> The reaction is carried out at 30-80°C. The resin from o-toluidine solidifies to a colophony-like mass, and has a softening point of 60°C. The addition of a salt of the amine or a further amount of the aldehyde increases the softening point. A bright yellow resin, softening at 80-85°C., is produced by heating 100 parts of o-toluidine and 70 parts of 94 per cent alcohol to boiling and adding 115 parts of formaldehyde with 0.4 part of formic acid.<sup>89</sup> Chlorotoluidines (1 mol) in alcohol (90 per cent) and 30 per cent formaldehyde (1.4 mols) gave a resin softening at 30°C., while  $\alpha$ -naphthylamine (1 mol) and formaldehyde (1.15 mols) gave one melting at 125°C. The yield of resin was improved, and its softening point was raised, on adding up to 10 per cent of a salt of the amine to the free amine employed. These resins are resistant to alkali, and may be used as resists in batik dyeing and printing.<sup>90</sup> They can be removed from the fabric by organic solvents, by weak acids or by treatment with hot water. The resins form brittle, clear yellowish to brownish masses of conchoidal fracture, which are soluble in many of the usual organic resin solvents. Solutions of the resins yield clear films (on glass, porcelain or metal) which are reported to be air-proof and, in some instances, light-proof.

On allowing the molten resin from naphthylamine residues to fall into a 40 per

cent solution of formaldehyde containing 37 per cent of hydrochloric acid, and then heating for a short time to 300°C., an odorless resin with a softening point of 120°C. is obtained.<sup>91</sup> A novel application of amino resins, namely, in photography, is due to Beebe, Murray and Herlinger.<sup>92</sup> The following example illustrates the process: 35 g. of dimethylaniline, 14 g. of benzaldehyde and 4 g. of iodine are mixed and allowed to stand at room temperature for about 3 days. The result is a viscous green product. Through the addition of 1 g. of iodoform to 10 g. of the resin, a light-sensitive coating is produced which gives a print in about two minutes by optical projection in the usual manner. Benzylaniline, formaldehyde, water and a trace of concentrated hydrochloric acid likewise give a condensation product. When this is dissolved in benzene and iodoform added, the solution will give a light-sensitive film yielding a print in 30 seconds. The print may be developed with benzene and turpentine. The principal feature of this process is that the synthetic resin is capable of being condensed under the action of light, the iodine or organic iodine compound serving as a sensitizer. The condensed form of the resin is less soluble than the starting material, which introduces the possibility of obtaining a graded photographic image.<sup>93</sup>

As a substitute for copal and for resins used in sealing wax, Goldschmidt<sup>94</sup> proposed the employment of a resin formed by heating methylaniline or methyl-diphenylamine with formaldehyde and hydrochloric acid for 2 hours and then oxidizing.

At an earlier date, Goldschmidt<sup>95</sup> reported the formation of an unstable product of high molecular weight in the reaction between asparagine,  $\text{COOH}-\text{CH}(\text{NH}_2)-\text{CH}_2-\text{CO}-\text{NH}_2$ , and formaldehyde.

#### BENZYLANILINE RESIN

Goldschmidt's investigation led Herzog<sup>96</sup> to experiments on the condensation of secondary amines in which a benzyl group forms one component. A resin was obtained by heating for one hour (under reflux) 9 g. of benzylaniline, 10 g. aqueous formaldehyde (40 per cent), 20 cc. of water and 1 cc. of hydrochloric acid. A 94 per cent yield of a brittle, brownish yellow, transparent resin was the result. This product is probably a condensation of two mols of benzylaniline with one mol of formaldehyde to form dibenzyl-diaminodiphenylmethane,

and finally by rearrangement<sup>97</sup> yielding diphenyldiaminodibenzylmethane,

<sup>91</sup> A. Steindorff, German P. 378,067, 1922, to Farb. Meister, Lucius & Brünig; *J.S.C.I.*, 1923, 42, 1063A.

<sup>95</sup> C. Goldschmidt, *Chem. Ztg.*, 1893, 22, 374.

<sup>96</sup> W. Herzog, *Oester. Chem.-Ztg.*, 1921, 24, 16; *Chem. Abs.*, 1921, 15, 1410.

<sup>97</sup> Note German P. 58,072, 1890, to Farb. vorm. Meister, Lucius & Brünig; *Chem. Zentr.*, 1891, 2, 888.

The resin is easily soluble in benzene and trichloroethylene in the cold, and dissolves in turpentine on heating. When the resin is prepared in alcohol as a diluting medium, the product exhibits a redder tone. Neither organic acids nor alkalis act as resinifying agents. The product differs from the resin obtained by Goldschmidt in that the reaction proceeds only to the formation of diphenylmethane derivatives, which according to Herzog furnish a stable resin of use in the varnish industry, while Goldschmidt's resin from methylaniline and methyl-diphenylamine is a more complex product said to be subject to partial oxidation on exposure to air with the formation of strongly colored substances. Hence Herzog regarded Goldschmidt's resin as useful only for sealing wax.

#### NAPHTHYLAMINE RESINS

Acetaldehyde reacts with  $\beta$ -naphthylamine and with mixtures of  $\alpha$ - and  $\beta$ -naphthylamine in the presence of solvents, e.g., benzene, to form a hard resinous compound and a product resembling Canada balsam, respectively. These products have been proposed for use in the manufacture of varnishes and tracing paper. A product resembling rosin can be prepared by treating a mixture of equal parts of  $\alpha$ - and  $\beta$ -naphthylamine with formaldehyde; the mixture is agitated at 100°C., and, after cooling and separating the aqueous layer, the material is purified by kneading under hot water and is dried at about 120°C. A mixture of  $\alpha$ -naphthylamine and xylydine may also be used.<sup>18</sup>

Aniline, toluidine, xylydine or naphthylamine, alone or mixed, are condensed with acetaldehyde, aldol or crotonaldehyde (or mixtures of these compounds) by heating at 80-100°C. in a varnish solvent with the addition of a small amount of a condensing agent such as oxalic acid.<sup>19</sup> Benzene and its homologues, solvent naphtha or tetrahydronaphthalene are the usual solvents. Varnishes are obtained which dry quickly and yield a bright surface, stable to water and alkali. Soluble dye-stuffs may be added and also linseed oil or copal. As an example of the preparation of this type of varnish,  $\alpha$ -naphthylamine is dissolved in xylene, oxalic acid is added and the mixture is treated at 80°C. with a xylene solution of acetaldehyde. Caustic soda is then added, and the sodium oxalate which forms dissolves in the water produced in the reaction and is removed. The odor of the varnish is pleasant and bears no resemblance to that of  $\alpha$ -naphthylamine. A mixture of acetaldehyde, aldol and crotonaldehyde may be condensed in boiling solvent naphtha with  $\alpha$ -naphthylamine and aniline, in the presence of concentrated hydrochloric acid, and the acid removed with caustic soda or ammonia. When the solution is treated with naphtha-soluble black and diluted further with the solvent a deep black, rapid-drying varnish with a high luster is obtained.

Manfred, in a process for the manufacture of horn-like masses with elastic properties, used an albuminous material with, among other possibilities, an aldehyde-amine condensation product.<sup>20</sup> N-Methyl-p-aminophenols are prepared by reducing the condensation product of the corresponding p-aminophenol and formaldehyde with activated aluminum in alkaline solution. Reduction and condensation may be effected in a single operation.<sup>201</sup> Böhler<sup>202</sup> found that mixtures of phenol-formaldehyde or resinitannol-formaldehyde and amine-formaldehyde resins, prepared either by fusing the components together or by using a common solvent,

<sup>18</sup> German P. 300,685 and 303,953, 1917, to Farb. vorm. Meister, Lucius & Brünig; *J.S.C.I.*, 1922, 41, 382A.

<sup>201</sup> British P. 306,939, 1923, to Chem. Fabr. Grünau Landshoff & Meyer A.-G.; *Chem. Abs.*, 1929, 23, 519B.

<sup>202</sup> C. Böhler, German P. 545,270, 1929; *Chem. Abs.*, 1932, 26, 3126.

gave products which hardened less readily than the phenol or tannol resin alone, and could be used for making molded articles. A yellow resin, to which the name A.F.S. has been given, was prepared by the condensation of aniline, formaldehyde and sulphur. It appears to be serviceable as a substitute for Canada balsam in mounting microscopic objects, and is used in the same manner.<sup>108</sup>

#### RESINS FROM AMINES AND OTHER ALDEHYDES

To a certain extent the processes already described using formaldehyde for resin production may be applied without further modification so as to utilize other aldehydes. The present section is devoted, however, to the description of a number of reactions in which these higher aldehydes are mentioned specifically.

The condensation products prepared from a primary or a secondary amine (o-toluidine, m-xylydine or cresidine) with an aliphatic aldehyde (e.g., formaldehyde, acetaldehyde or crotonaldehyde) in the presence of hydrochloric acid are proposed mordanting agents for dyeing (with acid and chrome colors) vegetable fibers, viscose and cupranmonium silks. The formaldehyde-o-toluidine product, e.g., gives insoluble lakes with acid and chrome dyes. The mordant may be used on wool, silk, leather or furs, but not on cellulose acetate fabrics.<sup>104</sup>

Crotonaldehyde, condensed with amines such as aniline or  $\alpha$ -naphthylamine, in the absence of a condensing agent forms synthetic resins.<sup>105</sup> When aniline is gradually added to crotonaldehyde at a temperature below 50°C., the mixture being stirred for 3 hours and allowed to stand and finally heated *in vacuo* to 125°C., a brittle resin forms. The reactants may be dissolved in solvents (benzene, acetone or alcohol).<sup>106</sup>

A synthetic resin prepared from aniline and furfural was found by Moss and White<sup>107</sup> to be compatible with cellulose acetate. When added to lacquers containing the latter, clear solutions were formed, which, on drying, produced clear, hard, tough and firmly adherent films, brown in the undyed or unpigmented form. In the preparation of the resin, equimolecular proportions of furfural and aniline are heated under reflux for from 1 to 3 hours at 170°C. The brittle, black resin formed is soluble in acetone or benzene, the solution in acetone being miscible with cellulose acetate solutions in the usual solvents. These resins lighten in color on exposure to light, whereas phenol-formaldehyde resins darken. A mixture of the two resins is reported to give a light-fast film. The following is the composition of a mixture for producing such a film:

Cellulose acetate . . . . .	10 parts
Aniline-furfural resin . . . . .	5 "
Phenol-formaldehyde resin . . . . .	5 "
Acetone . . . . .	100 "

Natural resins, plasticizers and pigments may also be incorporated in these resins.

Acetaldehyde or furfural-amine resins may be used in impregnating a fibrous pulp, as already described in the case of formaldehyde-aniline resins.<sup>108</sup> Furfural may also be condensed with the fusible reaction product of an aromatic

<sup>108</sup> R. H. Kienle and W. J. Scheiber, British P. 352,140, 1929, to British Thomson-Houston Co., Ltd.; *Chem. Abs.*, 1932, 26, 4144.

amine and formaldehyde (formed with not more than 0.2 mol of acid per mol of amine), a filler may be added and the product hardened by hot compression.<sup>100</sup> Cinnamaldehyde and aniline yield a synthetic resin.<sup>100</sup> Aromatic amines have also been reported as reacting with  $\alpha,\beta$ -disubstituted acraldehydes forming condensation products.<sup>101</sup> Cherry and Kurath<sup>102</sup> found that a condensation would take place between amines, organic acids and aldehydes, forming wax substitutes and plasticizing agents. The aldehydes used include formaldehyde and furfural. Appropriate acids are stearic, succinic, benzoic and oleic, and also rosin. Aniline, toluidine or naphthylamine represent types of amines which may be employed. As an example, 30 parts of rosin are heated to 170-200°C. with 10 parts of aniline for 3 hours. Nine parts of furfural are added and the heating continued at 200°C. for half an hour. The product is not as brittle as rosin, and has a plasticizing effect on phenolic molding compositions.<sup>103</sup> When half of the rosin is replaced by stearic acid, a substance with both wax-like and resinous characteristics results. Shepard<sup>104</sup> found that products such as those formed in the condensation between acetaldehyde and aniline may be freed from water by melting with about 10 per cent of a fatty acid (stearic acid) and heating to evaporate the water.

Huxham<sup>105</sup> added 90 parts of a furfural-aniline resin to 100 parts of a fusible phenol-aldehyde condensation product dissolved in a high-boiling hydrocarbon solvent. The mixture is hardened at 150°C. for several hours and may be used as a cold-molding composition for the manufacture of insulators. Powell<sup>106</sup> has made use of the synthetic resins from amines and aldehydes for preventing the rancidification of soap. Thus, 0.02 to 0.5 per cent of the product from aniline and acetaldehyde was sufficient. It is possible to add the amine to the raw oil or fats prior to their saponification, and to add the aldehyde to the saponified product, the two substances reacting while incorporated in the soap.

A mixture of dimethylquinol and aniline on standing for a long period yields an oil which, on distillation, gives a soft resin.<sup>107</sup> Carnahan and Hurd<sup>108</sup> obtained a yellow resinous solid melting at 76°C. by holding a mixture of acrolein and aniline at 10°C. On heating this mass it changed into higher-melting resins.

#### MISCELLANEOUS PRODUCTS FROM AMINES

Daniels and Snell<sup>109</sup> have used diphenylguanidine and triphenylguanidine for hardening shellac. The following example illustrates the method of working. A mixture of shellac (50 lb.), denatured alcohol (15 gallons), triphenylguanidine (0.5 lb.) and wood flour (300 lb.) is thoroughly dispersed, and the alcohol then removed. Hot molding of the powdery product gives a finished article which is resistant to alcohol, and remains hard at temperatures considerably above the softening point of natural shellac. Other agents which produce the same effect are aldehyde-ammonia, an aminonaphthalene, a secondary aromatic amine, a

piperidine-carbon disulphide addition product, and sodium  $\beta$ -naphthoxide. The condensation product of aldol and diphenylguanidine is used by Chamberlain<sup>120</sup> to retard the action of the acid in a pickling bath on the metal itself, without interfering with the removal of scale or oxide. The products from formaldehyde, acetaldehyde or heptaldehyde and aniline, and those from furfural and diethylamine or diphenylguanidine may be used for the same purpose.

Polymerization products of amides or imides with an aldehyde find use as bonding agents for abrasives on paper and other materials.<sup>121</sup> A molding composition for the production of insulators may be made by combining coal residues with aromatic amines.<sup>122</sup> Resins have also been obtained from amines, aldehydes and drying oils. Thus a viscous oil is formed from tung oil, phenylamine and phenylamine hydrochloride. This oil is heated with anhydroformaldehyde/aniline for 1-2 hours at 200°C. and then treated with formaldehyde to give the final product.<sup>123</sup>

### ACETYLENE CONDENSATIONS

Acetaldehyde, prepared by passing acetylene at 25 pounds per square inch into 25-35 per cent sulphuric acid containing mercurous sulphate at 68-80°C., may be removed from the gaseous reaction product by combination with a primary amine (e.g., aniline, toluidines or xylidines). Absorption takes place in a series of four scrubbing towers, each followed by a condenser and trap for removal of water formed. The acetylene escaping from the final tower is scrubbed and returned to the circuit.<sup>124</sup>

Resin-like condensation products are formed on treating primary aromatic amines with acetylene in the presence of a catalyst (a mercury compound) and in the absence of water or alcohol. Thus, aniline treated with acetylene in the presence of mercuric chloride gave a red resin, which melted at 70-104°C.<sup>125</sup> These products are applied as lacquers or alkali-resistant varnishes and, in the rubber industry, as vulcanization accelerators and anti-oxidants; they may also be converted into new products by sulphonation, nitration, reduction or by treatment with aldehydes. As an example of the method, 280 parts of aniline are stirred into 27 parts of mercuric chloride in an atmosphere of acetylene at 30-50°C., until no more of the gas is absorbed. The product is dissolved in mineral acid, and the mercury deposit is filtered off. A reddish resin remains after removing unchanged aniline by steam distillation.

When acetylene and aniline vapors are passed over alumina at 360-420°C., lepidine is formed. The same product can be obtained from acetaldehyde and aniline at 400-500°C.<sup>125a</sup> Matheson<sup>126</sup> conducted acetylene into aniline at 90°C. in the presence of cuprous chloride as a catalytic material, and found that the substances combined in approximately equimolecular proportions. On fractionally distilling the product, the fraction boiling at 200-275°C. having a formula believed to

be  $C_6H_5-NH-CH=CH_2$ , was isolated and allowed to react with acetaldehyde. The product had good qualities as a rubber vulcanization accelerator.

Rötger and Schlecht<sup>127</sup> obtained a tar-like mass by heating acetylene, aniline vapor and steam to 350°C. in contact with a catalyst obtained by soaking silica gel in zinc nitrate and heating. Silica gel is an efficient catalyst for the alkylation of aniline, but is fouled by the polymerization products resulting from the combination of acetaldehyde (formed in the above reaction) and aniline.<sup>128</sup> The reaction between acetylene and aniline at higher temperatures (e.g., 700°C.) with a catalyst (e.g., nickel, silica or platinum) gave indole.<sup>129</sup>

#### AMINE-ALDEHYDE CONDENSATION PRODUCTS AS VULCANIZATION ACCELERATORS

Bysov<sup>130</sup> stated that any substance soluble in rubber and capable of dissolving sulphur would function, by aiding the distribution of sulphur, as a vulcanization accelerator, and that any substance soluble in rubber and able to form a precipitate insoluble in rubber would serve in a like manner.

The role of aniline as an accelerator of rubber vulcanization was studied by Kimishima<sup>131</sup> who found that, at the temperature of hot vulcanization, aniline reacts with sulphur giving hydrogen sulphide, dithioaniline and a small quantity of thioaniline and resinous materials. In an atmosphere of hydrogen sulphide, dithioaniline acts as a powerful accelerator. The mechanism of the accelerating effect is given as follows:

Investigators in the rubber industry have found that many amine-aldehyde condensation products are satisfactory as vulcanization accelerators.<sup>132</sup> Representatives of the following combinations have been prepared and are mentioned later in this chapter: primary aromatic amines with saturated aliphatic aldehydes, primary aromatic amines with aromatic aldehydes, primary aromatic amines with unsaturated aliphatic aldehydes, primary aliphatic amines with aliphatic aldehydes and ammonia with unsaturated aldehydes. Also, secondary amines and urea have been employed. Several investigators have used acid condensing agents. The proportions of aldehyde to amine have been varied and the initial reaction products have been combined with further amounts of aldehyde. Finally, the preparation of vulcanization accelerators has been varied by combining carbon disulphide or various mercaptothiazoles with the amine-aldehyde condensation products.

An example of the use of these amine-aldehyde condensation products is the semi-vulcanized gasket formed by incorporating with rubber the reaction product of an aliphatic aldehyde (3 mols) and a primary aromatic amine (2 mols) as described by Smith and Schreiner.<sup>133</sup> Rubber to be used in the manufacture of various other products is combined with fragments, softening at 80-150°C., formed from colophony and aldehyde-aniline accelerators.<sup>134</sup>

Cadwell<sup>135</sup> condensed aniline and acetaldehyde in a water medium having a hydrogen ion concentration between  $1 \times 10^{-3}$  and  $2.5 \times 10^{-6}$  to produce a rubber vulcanization accelerator. A higher acid content lessens the accelerating proficiency, and too little acid decreases the yield of the product. The reaction temperature used is 135-140°C.<sup>136</sup> and other starting materials include: heptaldehyde and aniline, heptaldehyde and ammonia, butyraldehyde and aniline, aldol and aniline, nonaldehyde and aniline and heptaldehyde with ethylamine, p-toluidine, benzidine, p-phenylenediamine, p-aminodimethylaniline or urea.<sup>137</sup> Halogen derivatives of the condensation products are also employed.<sup>138</sup> In the condensation, aldehydes with a chain of carbon atoms (i.e., higher than formaldehyde) are preferred.<sup>139</sup> The reaction between 2 mols of an aldehyde (formaldehyde, acetaldehyde, benzaldehyde), 2 mols of a primary amine (aniline, ethylamine, isopropylamine, hydroxyethylamine) and 1 or 2 mols of carbon disulphide was shown by Powers<sup>140</sup> to give accelerators. Similar products result when an aldehyde is treated with a substituted ammonium salt of a mono-substituted dithiocarbamic acid. Sebrell<sup>140a</sup> accelerated vulcanization by employing an acetal-dol-aniline reaction product. Mercaptonaphthothiazoles and mercaptomethylthiazoles combined with the reaction products of various aldehydes and primary amines perform a similar function,<sup>140b</sup> for the resulting resinous compounds are easily dispersed in rubber. The reaction product of 2-mercaptobenzothiazole (2 mols) with 2,4-diaminodiphenylamine (1 mol) condenses with acetaldehyde (1 mol), crotonaldehyde (1 mol), butyraldehyde and heptaldehyde yielding accelerating compositions.<sup>141</sup> Using aldehydes, having a hydroxyl group substituted in an aromatic nucleus, and amines, Teppema<sup>142</sup> obtained rubber accelerators that also improved the quality of the final product. Thus, 1 mol of  $\beta$ -hydroxynaphthaldehyde is refluxed for several hours with aniline. A yellow crystalline compound is obtained which on heating evolves an oil and leaves a resinous mass. This resin has accelerating properties not possessed by the yellow crystalline compound.

Scott<sup>143</sup> treated the amine-aldehyde reaction products with additional aldehyde to give accelerating substances. As an example, 1 mol of aniline is heated at 80°C. with 1.5 mols of acetaldehyde or a higher homologue, and 40 per cent formaldehyde is added to the resulting material. A slightly modified procedure involves heating the amine-aldehyde product with formaldehyde or acetaldehyde at 95°C. under increased pressure for 4 hours, and then under reduced pressure.<sup>144</sup> The amine-aldehyde may also be treated, below 30°C., with 2

<sup>144</sup> C. O. North, U. S. P. 1,639,957, Aug. 23, 1927, to Rubber Service Lab. Co.; *Chem. Abs.*, 1927,

per cent of concentrated hydrochloric acid, neutralized and then heated with formaldehyde or acetaldehyde.<sup>143</sup> Alternatively, the reaction can take place by heating at 100°C. and dehydrating at 105°C.<sup>144</sup> North<sup>147</sup> prepared similar products from aniline and acetaldehyde by subsequent reaction with additional acetaldehyde or other aliphatic aldehyde higher than formaldehyde. He also formed compounds from the reaction of carbon disulphide on these aldehyde derivatives of the Schiff's bases.<sup>148</sup> An accelerating composition was prepared by North<sup>149</sup> by combining the reaction product from 3 mols of butyraldehyde and 1 mol of aniline with the product from 3 mols of acetaldehyde and 2 mols of aniline in a mixture of creosote oil and pine oil. The product of the condensation of butyraldehyde and aniline, on evaporating off the water formed and heating at 100-145°C. for 2-20 hours, serves as an accelerating agent.<sup>150</sup> North and Christensen<sup>151</sup> employed crotonaldehyde and aniline as the basis for an accelerator.

In the process of Cambron,<sup>152</sup> aldehyde-amine accelerators are produced, without the use of excess aldehyde, by condensing the reagents without water in the presence of acidic substances (e.g., zinc chloride, hydrochloric or sulphuric acid, aluminum chloride, chlorodinitrobenzene). No solvent is used and the product can be finely ground without danger of subsequent lumping. An accelerating resin, from aniline and aliphatic aldehydes, known as "Vulcone," retards pre-vulcanization in rubber compositions and is said to improve the plasticity of the product.<sup>153</sup>

Unsaturated aldehydes also are employed in the preparation of vulcanization accelerators. Morton<sup>154</sup> used  $\alpha$ -ethyl- $\beta$ -methylacrolein with an amine (aniline), neutralized by abietic acid, in making a stable agent.  $\alpha,\beta$ -Dialkyl-substituted acroleins were also employed by Kropp<sup>155</sup> to react with aniline in the presence of an inert solvent (benzene) and a condensing agent (zinc chloride). The reaction product of an unsaturated aldehyde (crotonaldehyde) and an amine gives a vulcanizing accelerator.<sup>156</sup> Unsaturated aldehydes with conjugated double linkings and aromatic amines serve the same purpose.<sup>157</sup> Williams and Burnett<sup>158</sup> made

The deterioration of amine-aldehyde compounds (e.g.,

various amine-aldehyde products for use in rubber vulcanization by allowing 2-20 mols of an aldehyde to react with an amino compound under conditions effecting the elimination of water.  $\alpha$ -Unsaturated aldehydes are excluded, and the condensation of n-butaldehyde with aniline or o-toluidine and heptaldehyde with n-butylamine is carried out in the presence of n-butyric, stearic, n-valeric, acetic or sulphuric acid. As the proportion of aldehyde in the product increases, the curing power rises to a maximum and then decreases. The condensation products of amines (aniline, butylamine or o-tolyl guanide) and saturated aldehydes (butyr-aldehyde, heptaldehyde or propionaldehyde) with, preferably, weak organic acids as condensing agents are unaffected by the presence of carbon black in the rubber mix.<sup>100</sup> Additional condensing agents used are oleic acid, salicylic acid, picric acid, hydrochloric acid, phosphoric acid, zinc chloride, amine salts and acid anhydrides or halides.

The amine-aldehyde products were treated with a higher fatty acid by Bridgwater and Slack<sup>100</sup> and then added to the rubber mix as accelerators. Thus, methylenediphenylimine, from aniline and formaldehyde at 70-80°C., is mixed with molten stearic acid and then incorporated in the rubber mix. Butylidenedianilide (from the reaction of 1 mol of butyraldehyde and 2 mols of aniline) or other alkylidenedianilines condense with heptaldehyde to form vulcanization accelerators.<sup>101</sup> The reaction product of heptaldehyde and aniline may also be combined with a halogen-substituted toluene derivative (e.g., benzotrichloride) in the preparation of accelerators.<sup>102</sup>

The condensation product of ammonia with an unsaturated aldehyde possesses accelerating properties.<sup>103</sup> Ammonia-aldehyde compounds, such as hexamethylenetetramine or crotonaldehydeammonia, and a mercaptobenzothiazole are treated with an aliphatic aldehyde (formaldehyde or aldol) to prepare accelerating substances.<sup>104</sup>

A secondary amine (dibenzylamine, 2 mols) reacts with an aldehyde (para-formaldehyde) and the product formed is treated while in ether solution with carbon disulphide.<sup>105</sup> Diethylamine with paraformaldehyde and piperidine with furfural may also be treated with carbon disulphide, and the resulting compositions find use as accelerators in the vulcanization of rubber with sulphur.<sup>106</sup>

Shepard and Adams<sup>107</sup> mixed a water solution of hexamethylenetetramine with ethyl chloride in an autoclave and heated the addition product to effect hydrolysis. The compound formed is triethyltrimethylenetriamine which may be separated by settling after the addition of sodium hydroxide, and it is used to accelerate vulcanization.

The reaction product of an amine and an aldehyde-bisulphite compound was condensed by Fritzsche<sup>108</sup> with an aldehyde forming vulcanization accelerators.

aniline-heptaldehyde) can be prevented by treatment with a polyhydroxy compound (S. I. Strickhouser, U. S. P. 1,805,194, May 12, 1931, to Naugatuck Chem. Co.; *Chem. Abs.*, 1931, 25, 3669. Thus, formaldehyde condensed with sodium anilinemethane- $\omega$ -sulphonate and crotonaldehyde condensed with sodium aniline-ethane- $\alpha$ -sulphonate,

give products with the desired properties.

#### RUBBER PRESERVATIVES

Certain amine-aldehyde combinations preserve rubber compositions from rapid deterioration. Several terms are used to denote the function of these compounds; they are known as antioxidants, anti-agers and age-retarders. The protective action of antioxidants, according to studies made by Kohman,<sup>169</sup> is a negative catalysis rather than a preferential absorption. On the other hand, Kirchhof,<sup>170</sup> in a study of aldol- $\alpha$ -naphthylamine, found that anti-agers have intense colorations with certain metallic chlorides (ferric and cupric chloride) and considered the products analogous to hæmin inasmuch as the catalytic effect was suppressed by hydrogen cyanide.

Naunton<sup>171</sup> classified antioxidants as natural, physical or chemical. The chemical antioxidants, which include the amine-aldehyde preservatives, are chiefly of use for protection against heat-induced oxidation, and serve poorly as protection against light.

Deterioration retarders from 1 mol of  $\alpha$ -naphthylamine condensed with 2 mols of acetaldehyde in an inert solvent were made by Robinson.<sup>172</sup> These products may be heated to fusion with 0.3-0.5 mol of other aromatic amines (diethylaniline, dimethylaniline,  $\beta$ -naphthylamine) forming clear, brittle resins also used with rubber as age-resistors.<sup>173</sup> Cronshaw and Naunton<sup>174</sup> combined equal proportions of  $\alpha$ - and  $\beta$ -naphthylamine and condensed the mixture with acetaldehyde in the presence of hydrochloric acid. The addition of 1.5 per cent of the product imparts good aging properties to rubber compositions.  $\alpha$ -Naphthylamines and aliphatic aldehydes may be condensed in the presence of water-soluble alcohols and acids, and the resins formed are further treated with water.<sup>175</sup> Yellowish, odorless powders are obtained which are antioxidants and do not interfere with normal vulcanization. Acetaldehyde, aldol and crotonaldehyde are examples of aldehydes employed, and the acids used are formic and acetic.

Aldol- $\alpha$ -naphthylamine was found by Winklemann and Gray<sup>176</sup> to increase the durability of rubber and to have no accelerating effect on vulcanization. This com-

pound (known as "agerite resin"<sup>177</sup>) was studied by Chesnokov<sup>178</sup> who found that phenyl- $\beta$ -naphthylamine had the same action on rubber. Thermoplastic unvulcanized insulating compounds for deep-sea cables containing rubber, gutta-percha, balata and a plasticizer were preserved by Kemp and Ingmanson<sup>179</sup> with small amounts of aldo- $\alpha$ -naphthylamine, acetaldehyde-ethylenediamine<sup>180</sup> and other anti-oxidants.

By reacting aniline and acetaldehyde at low temperatures (approximately 0°C.), Sebrell<sup>181</sup> produced a rubber preservative that is not a vulcanization accelerator. Crotonaldehyde and an aromatic amine, likewise, can be used to retard rubber deterioration.

Aldehydes and diarylamines were condensed by Semon<sup>182</sup> and resinous, non-accelerating products were obtained that are used as antioxidants in vulcanized rubber and as retarders of resinification and as depressants of tack in raw rubber. The reagents used include butyraldehyde, aldol, or formaldehyde with diphenylamine, phenyl- $\beta$ -naphthylamine, dinaphthylamine or sym-diphenyl-p-phenylene-diamine. Formaldehyde or aldol also gives anti-agers by reaction with diarylalkylenediamines (e.g., diphenylethylenediamine).<sup>183</sup> Unsaturated aldehydes and aniline or  $\alpha$ -naphthylamine yield effective deterioration retarders when condensed in an acid medium.<sup>184</sup> Scott<sup>185</sup> employed 2 per cent of the reaction product of a Schiff base (e.g., crotonaldehyde-aniline) with phenol or  $\alpha$ - or  $\beta$ -naphthol in curing rubber. Iodine was utilized as a catalyst and the resulting substance was directly incorporated in the rubber mix prior to vulcanization.

Equimolecular proportions of butyraldehyde and a primary aromatic amine condensed in the presence of at least 0.03 mol of a weak organic acid per mol of aldehyde were found by Williams<sup>186</sup> to be age-resistors for rubber. Rubber contained in plants of the guayule type, after harvesting and during extraction, was treated for preservation by Spence<sup>187</sup> with a dilute solution of an amine-aldehyde condensation product.

The material formed by heating together aniline, acetone and phenol or  $\beta$ -naphthol was made by ter Horst<sup>188</sup> as an antioxidant. As an example of this investigator's procedure, 144 g. (1 mol) of  $\beta$ -naphthol, 93 g. (1 mol) of aniline, 500 g. of acetone and 2 g. of iodine are heated at 200-220°C. in a rotating iron autoclave for 24 hours. A quantity (722 g.) of a dark-brown liquid is obtained, from which the excess of acetone, the water formed in the reaction and unreacted aniline are removed by distillation. The product, a heavy oil, gave good results as an antioxidant when tested in a carbon black stock consisting of 100

<sup>177</sup> Agerite resin is prepared by the condensation of equimolecular proportions of acetalal with  $\alpha$ -naphthylamine. It is a cherry-red product, brittle at low temperatures and liquid at 100°C. (P. I. Murrill, private communication). See also R. T. Vanderbilt Co., *Vanderbilt News*, 1931, 1 (3), 4; *Chem. parts of smoked sheet, 10 parts of zinc oxide, 42 parts of carbon black, 3.25 parts of stearic acid, 3.25 parts of sulphur, 3.5 parts of pine tar and 1.25 parts of mercaptobenzothiazole. Coleman<sup>120</sup> treated aniline with formaldehyde at 40°C. for 2 hours, separated water, and added aniline hydrochloride. The mixture is then heated at 80°C. for 24 hours, the acid is neutralized and water and unreacted aniline distilled off. The product, 4,4'-diaminodiphenylmethane, or its combination with 0.5-1 mol of formaldehyde may be used to retard rubber aging. In strongly acid solution, 1 mol of aliphatic aldehyde gives rubber protective agents with 1 mol of an aromatic amine (aniline, o-, m- or p-toluidine, monomethylaniline or 4-amino-1,3-xylene).<sup>120</sup> The hexahydro-1,3,5-triazines obtained from formaldehyde and ethylamine are both accelerators and anti-agers. Cadwell<sup>121</sup> obtained the anti-aging effect by using an excess of the reagent over the amount required for vulcanization and by using a smaller proportion of sulphur.

A small quantity of the resinous or syrupy product obtained by the interaction of a mono- or polysaccharide and an amine was found by Källner<sup>122</sup> to effect age-retarding in rubber. Aldoses and ketoses may be used with aniline,  $\alpha$ - and  $\beta$ -naphthylamine, m-toluylenediamine, urea or p-aminophenol.

#### MISCELLANEOUS COMPOSITIONS

When the benzylidene derivatives of aromatic amines are heated, resin formation is observed (as already noted). Thus, for example, benzylideneaniline, heated with 25 per cent hydrochloric acid at 150°C., gave an elastic resin, insoluble in acids and alkalis but soluble in benzene and linseed oil. A similar product is obtained by heating  $\alpha$ -naphthylamine, benzaldehyde, solvent naphtha and 25 per cent hydrochloric acid together under reflux. The products are elastic and good insulators. Fillers may be added either before, during or after formation of the resins.<sup>123</sup>

The condensation of primary aromatic amines with derivatives containing active methylene groups (formaldehyde, anhydroformaldehydeaniline, anhydro-p-aminobenzyl alcohol) at a temperature below 120°C. in acid media yields polynuclear amino bases that may be used as additions to pickling acids, in the rubber industry or as starting materials for the preparation of resins.<sup>124</sup> These polynuclear bases have their nuclei directly or indirectly linked by methylene groups (present in the proportion of less than 2 methylene groups for each 2 mols of aromatic residue) and yield thermoplastic and thermohardening resins when condensed with aldehydes.<sup>125</sup> Mono- or polynuclear phenols or phenolic esters which contain active  $-\text{CH}_2$  groups have also been condensed with aromatic amines to give resins having low molecular weights.<sup>126</sup>

As an example, 1 mol of diaminodiphenylmethane in alcohol is heated with 2 mols of formaldehyde. The product is treated with aniline and glacial acetic acid and kneaded with wood flour, salicylic acid and formaldehyde. It is then dried, molded and heated.<sup>127</sup>

The addition of between 0.5 and 1 per cent of the condensation product of acetaldehyde and aniline to oil, used in impregnating paper for the wrapping of cables, is found to prevent deterioration of the oil. Lubricating oils and transformer oils may be protected from deterioration by a similar addition. The products from other aldehydes (e.g., formaldehyde, benzaldehyde, furfural or aldol) with other amines (e.g., aniline,  $\alpha$ - and  $\beta$ -naphthylamine or ammonia) may be used for the same purpose.<sup>198</sup>

Compositions which are mixtures of organic polysulphide plastics and aldehyde-arylamine resins have been prepared. The products are obtained by dissolving the reactive halogenated hydrocarbon and alkali polysulphide in the amine and then adding the aldehyde.<sup>199</sup>

A mixture of an amine-aldehyde resin with an alkaline solution of a phenol-aldehyde condensation product in a water-miscible solvent forms a precipitate that may be used as a molding powder after neutralizing, washing and drying.<sup>200</sup> The amine-aldehyde resin is prepared by condensing the amine with aqueous formaldehyde at room temperature in the presence of water. The phenol-aldehyde product is used when in the soluble or "A" phase with a cure of 30-120 seconds on a hot-plate heated to 160°C. In electrical insulation products from phenol-aldehyde and other resins, the surface-leakage paths are reduced by applying an amine-aldehyde resin as a covering layer. The amine resin is scattered on the article during the pressing operation.<sup>201</sup>

Non-sulphonated, water-soluble amine-formaldehyde resins are applied to hides previous to tanning. The tanning process is accelerated by these compounds either alone or with dilute tanning solutions or a mixture of alum and Glauber's salt.<sup>202</sup>

Resins formed by condensing aromatic amines with aldehydes in the absence of solvents and with filling materials, catalysts, pigments and plasticizers are used in the manufacture of pressed articles.<sup>203</sup>

## Chapter 34

### Sulphonamide-Aldehyde Resins

The development of sulphonamide-aldehyde resins has been largely a result of efforts to utilize p-toluenesulphonamide, a by-product in the manufacture of saccharin.<sup>1</sup> The latter is made from toluene as indicated by the following series of formulas.<sup>2</sup>

Toluene when treated with an excess of chlorosulphonic acid yields first, toluene o-sulphonic acid and then toluene o-sulphonyl chloride. The treatment of this latter compound with ammonia yields toluene o-sulphonamide, which, on oxidation, is converted into o-benzoic sulphonamide, and finally into saccharin, with the loss of 1 molecule of water.<sup>3</sup>

In the sulphonation of toluene both the ortho and para sulphonic acids are formed, which by the above reaction are converted into the corresponding sulphonamides. The ortho compound on oxidation yields saccharin, whereas the oxidation product of the para compound is tasteless, and therefore of no value in this particular synthesis. Hence other uses have been sought for the p-sulphonamide.

One of the results of this search has been the production of sulphonamide-aldehyde resins. (See Fig. 117). It was found that p-toluenesulphonamide and formaldehyde in equimolecular proportions condense to a semi-solid or viscous mass, which when heated to 110°C. yields a hard colorless resin.<sup>4</sup> A mixture of o- and p-toluenesulphonamides when heated at 110-120°C. with paraformaldehyde yields a brittle resin. If p-toluene-sulphon-ethylamide is heated with formaldehyde and hydrochloric acid a soft resin is formed.

It was then found that a great number of sulphonamides can be used, including ortho-, meta- and para-toluenesulphonamides, naphthalenesulphonamide, halogenbenzene- and nitrobenzenesulphonamides and N-mono-alkyl derivatives of these sulphonamides.<sup>5</sup> The resins formed from such compounds are soluble in alcohol and acetone, giving clear varnishes and lacquers which are not affected by light. If the sulphonamides of tetrahydronaphthalene or its N-mono-substituted derivatives are condensed with formaldehyde,

<sup>1</sup> A discussion of this subject has been made by W. Herzog (*Kunststoffe*, 1926, 16, 105; *Chem. Abs.*, 1926, 20, 2910; "Die Verwertung der Nebenprodukte der Saccharinfabrikation," Ferdinand Enke, Stuttgart, 1926).

<sup>2</sup> See W. M. Cumming, I. V. Hopper and T. S. Wheeler, "Systematic Organic Chemistry," D. Van Nostrand Co., New York, 1931, 317.

<sup>3</sup> The original work on saccharin was performed by C. Fahlberg and I. Remsen (*Ber.*, 1879, 12, 469; *J.C.S.*, 1879, 35, 628).

<sup>4</sup> German P. 359,876, 1919, to Farb. vorm. Meister, Lucius & Brünig, *J.S.C.I.*, 1923, 42, 279A.

<sup>5</sup> German P. 369,844, 1919, to Farb. vorm. Meister, Lucius & Brünig; *J.S.C.I.*, 1923, 42, 614A.

resins are obtained which have higher melting points than those from the substances named above.\*

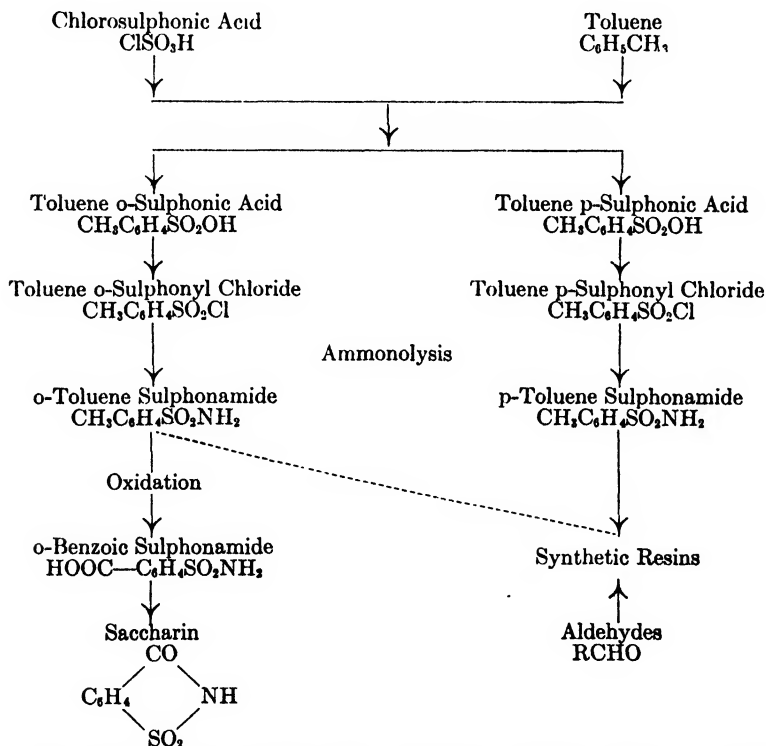

FIG. 117.—Flow Sheet for the Production of Toluene Sulphonamide as a By-Product in the Manufacture of Saccharin. Dotted line indicates that although o-toluene sulphonamide may be employed in resin-making, its principal use is the preparation of saccharin.

Sulphonamide-aldehyde resins were found to be compatible with cellulose esters and ethers and to increase the adhesion and clarity of lacquers. Moss and White<sup>7</sup> noted that ordinary p-toluenesulphonamide-formaldehyde resins were objectionable when mixed with cellulose esters because of their softness and because they con-

tain excess sulphonamide, which tended to form a "bloom" on the surface of films or plastics in which the resins were used. It was found that this fault could be remedied by heating the resin under reflux for 3 hours at 200-260°C. The product then has a melting point of 35-40°C. The same result can be obtained by adding to the reactants 5-10 per cent of urea.

Moss and White further noted that p-toluenesulphonamide-formaldehyde resin can be made to react with more sulphonamide to form a resin of higher melting point.\* A method used by them is as follows: Equimolecular proportions of p-toluenesulphonamide and formaldehyde are heated under reflux at 100-150°C. for 16-20 hours, yielding a soft, yellow resin. Purification with solvents and then heating in the open at 130-150°C. for 4-20 hours produces a hard, yellow resin, soluble in benzene. The addition of up to 25 per cent more p-toluenesulphonamide and further heating at 130-150°C. for 1-4 hours produces a clear, hard resin (melting at 64-75°C.) soluble in acetone, alcohol and benzene. This substance is completely compatible with cellulose acetate and is adaptable for non-blooming threads, films and molded articles. The procedure may be slightly modified by adding to the original reactants 5-10 per cent of urea.

The resin formed by using excess p-toluenesulphonamide was found to be unstable. When heated for 4-8 hours at 175°C. it changed into a dark, greenish-brown mass consisting of two crystalline substances, one melting at 140-150°C. and the other at 160-162°C. and both practically insoluble in benzene. If to the crystalline material up to 50 per cent of formaldehyde solution (40 per cent) is added and the mixture heated at 120-150°C. for from 6 to 12 hours, a soft, light brown mass is formed. Fusion of this mass in the open at 130-150°C. for 2-6 hours yields a transparent, light brown resin soluble in benzene and possessing a green fluorescence.\*

Other aldehydes besides formaldehydes have been utilized in making sulphonamide-aldehyde resins. Moss and White used furfural<sup>10</sup> and benzaldehyde.<sup>11</sup> Mixtures of aldehydes with urea, phenol, aniline or acetone have also been employed, producing complex resins.

The sulphonamides of aromatic ethers (e.g., etherified phenol, cresol, naphthol, resorcinol or pyrocatechol) may be substituted for p-toluenesulphonamide in making resins compatible with cellulose derivatives.<sup>12</sup>

Rispler, Luthy and Schilling<sup>13</sup> found that in the condensation of sulphonamides and aldehydes, the presence of acid condensing agents causes the formation of crystalline substances. For example: 100 parts of p-toluenesulphonamide are heated with 17-20 parts of paraformaldehyde at 100-150°C. until the mixture becomes a clear liquid. Then an acid condensing agent (0.1 to 3 parts of concentrated sulphuric acid or 0.5 to 6 parts of zinc chloride) is added, converting the liquid into a white, crystalline mass (m. p. 160-170°C.). A modified procedure involves addition of 20 parts of glacial acetic acid to the initial reactants at a lower temperature (60-120°C.) and the employment of more condensing agent (10 parts of either sulphuric acid or zinc chloride). Instead of paraformaldehyde, formaldehyde, trioxymethylene or polyoxymethylenes may be used. Also, other sulphonamides may be substituted which also

give crystalline substances. Usually these products when melted will not recrystallize on cooling, but form transparent, amorphous masses. They are similar to the resins of the other investigators mentioned and can be used for the same purposes. Analogous thermohardening resins are prepared by the reaction of formaldehyde with a phenol, urea (or urea derivatives), and an aromatic sulphonamide.<sup>14</sup> The amount of sulphonamide is not less than one-half of the amount of formaldehyde used. In one example 50 parts of p-toluenesulphonamide are used with 5 parts of phenol, 25 parts of urea and 150 parts of 37 per cent formaldehyde. The resins are soluble in low-boiling solvents and are said to be resistant to light.

Walter<sup>15</sup> prepared resins, which become infusible and insoluble when subjected to heat and pressure, by condensing aldehydes with aromatic sulphonamides containing, in addition to the sulphonamido group, at least one amino group, either as a carbamido group or as an additional sulphonamido group. Examples of these include m-sulphamidobenzamide, benzene-m-disulphonamide, mixed xylenedisulphonamides, and aniline-2,4,6-trisulphonamide.

Walter and his associates<sup>16</sup> have investigated the structure of sulphonamide-aldehyde condensates. Aryldisulphonamide-formaldehyde resin can be made infusible and insoluble, whereas arylmonosulphonamide-aldehyde resin cannot. These workers stated that the arylmonosulphonamide-aldehyde resins are probably made up of 3-membered methylenemethylolarylsulphonamide groupings carrying one terminal methylol group.

The above compound, dimethylenemethylol-tri-o-toluenesulphonamide, was obtained in crystalline form from an arylmonosulphonamide resin. It was found that the arylldisulphonamide-formaldehyde resin is also built up of methylene-methylol groupings which in many cases can be converted into di-methylene-arylsulphonamides of resinous character.

Walter and Storfer obtained resins from aryl sulphonamido carboxylic acid amides by condensation with formaldehyde. These resins are hydrophilic whereas the ordinary sulphonamide resins are hydrophobic. Attempts to resinify aryl dicarboxylic acid diamides with formaldehyde were unsuccessful.

In experiments of Walter and Lutwak, resins were obtained by the action of formaldehyde on 1,3,5-benzenetrisulphonamide, and phenol-2,4-disulphonamide. Resins from benzenesulphonanilide and from p-toluenesulphonanilide were obtained only in concentrated hydrochloric acid.

Aniline-m- and p-sulphonamide were found capable of yielding hardenable resins with formaldehyde or acetaldehyde, thus indicating that reaction could be made to take place with both the phenylamino and sulphonamide groups, in accordance with the theory that two reactive groups are necessary for the formation of infusible products. Occurrence of such radicals in the ortho position or acetylation of the amino group eliminates one reactive position. Thus aniline-o-

sulphonamide gave with acetaldehyde a crystalline monoethylidene compound and with formaldehyde a fusible resin. Furfural formed hardenable resins of complicated structure except in the case of acetylated derivatives, when crystalline monofurfurylene compounds were secured. Benzaldehyde reacted only with the nuclear  $\text{—NH}_2$  groups and therefore only crystalline bodies were obtained.<sup>17</sup>

Wood and Battye<sup>18</sup> prepared a light-stable, water-soluble amorphous substance by condensing a sulphonamide with formaldehyde, but with a dimethylsulphonamide a crystalline product resulted, insoluble in hot water and decomposing at about 185°C. They considered the reaction between p-aniline-sulphonamide and formaldehyde to yield a mixture of p-sulphonamide formanil ( $\text{CH}_2=\text{NC}_6\text{H}_4\text{SO}_2\text{NH}_2$ ) and p-aniline-N-methylolsulphonamide ( $\text{NH}_2\text{C}_6\text{H}_4\text{SO}_2\text{NHCH}_2\text{OH}$ ).

McMaster<sup>19</sup> concluded from his investigations that the resins from o- and p-toluenesulphonamides and trioxymethylene or formaldehyde consisted of C-N ring compounds, similar in structure to those made by Magnus-Levy<sup>20</sup> from benzenesulphonamide and formaldehyde. p-Toluenesulphonamide yielded, with formaldehyde or trioxymethylene, 1,3,5-tri-p-toluenesulphon-hexahydro-sym-triazine.

However, when Hug<sup>21</sup> carried out the same reaction in an acid medium he secured a resinous product which was considered to have the structure:

In place of the sulphonamide-aldehyde reaction, Hug used arylsulphonyl chlorides and hexamethylenetetramine, in alkaline solution, to obtain trimer bodies identical with the sulphonamide derivatives. For example, on stirring 1 mol of hexamethylenetetramine with 3 mols of p-toluenesulphonyl chloride at 60°C. in dilute sodium hydroxide solution, the above-mentioned cyclic trimer, p-toluenesulphon-hexahydro-sym-triazine, was formed.

When an alkyl derivative of p-toluenesulphonamide was used,<sup>21a</sup> no ring formation occurred. p-Toluenesulphonmethyamide yielded:

## USES OF SULPHONAMIDE-ALDEHYDE RESINS

The resins produced by Moss and White were recommended for use in conjunction with cellulose esters or ethers in the production of lacquers, plastic compositions, artificial yarns and threads, adhesives for shatterproof glass, and photographic films. The resins can be decolorized by dissolving them in acetone, alcohol or benzene, and treating the solutions with bone black, carbon black, activated charcoal, fuller's earth or silica gel at elevated temperatures.<sup>22</sup>

For convenience in classification, the uses of these resins will now be considered under separate headings.

## COATING COMPOSITIONS AND LACQUERS

A coating composition suggested by Moss and White<sup>22</sup> consists of toluenesulphonamide-aldehyde resin (1-20 parts) and cellulose acetate (10 parts) dissolved in acetone (100 parts). Instead of using acetone alone, the solvent may consist of acetone (50 parts), benzene (25 parts), alcohol (25 parts) and diacetone alcohol (20 parts). The same proportions of resin to cellulose acetate are used if the resin employed is that formed from an excess of toluenesulphonamide, but if a toluenesulphonamide-furfural composition is used the proportions are resin (10 parts), cellulose acetate (10 parts) and acetone (100 parts).<sup>24</sup> Other ketones, containing an unsaturated carbon linkage, such as methyleneacetone or methyl isopropenyl ketone, have been employed as solvents.<sup>25</sup>

Gardner<sup>26</sup> utilized toluenesulphonamide-aldehyde resin solutions directly as lacquers without the addition of other material, though he found that the lacquer is improved by the addition of natural resins and drying oils (1 per cent of each to a solution of p-toluenesulphonamide, 50 parts, in benzene, 50 parts). By using nitrocellulose with the sulphonamide resin, Gardner obtained a lacquer which formed very tenacious films on clean metal. The lacquer was made by mixing a solution of nitrocellulose in butyl or ethyl acetate with a solution of p-toluenesulphonamide-formaldehyde resin in benzene.

This same type of mixture was used by Gardner to produce a crystalline-finish lacquer.<sup>27</sup> To 100 parts of a solution of nitrocellulose (25 per cent) in butyl acetate are added 64 parts of a solution of powdered toluenesulphonamide-aldehyde resin (25 per cent) in acetone or ethyl lactate. The principle of the crystalline effect is that the resin is very soluble in acetone but only slightly soluble in butyl acetate. The acetone, being a low-boiling solvent, evaporates first, causing the sulphonamide-aldehyde compound to crystallize out in beautiful patterns. Use of ethyl lactate instead of acetone results in slower drying and the formation of larger crystals. For improved adhesion in lacquers of the cellulose acetate type, addition of a naphthalenemonosulphonamide-aldehyde resin is recommended.<sup>28</sup>

Benzene- or xylenesulphonamide-aldehyde resins were employed by Dreyfus<sup>29</sup>

in making coating compositions or adhesives by incorporating them with cellulose esters or ethers (e.g., cellulose acetate) and then adding other synthetic resins, natural resins, or plasticizers. The mixtures are dissolved in acetates, ketones or alcohols. Brominated tricresyl phosphate is sometimes added as a fire-retardant.<sup>30a</sup>

A coating preparation similar to this was suggested by Moss and White,<sup>30</sup> consisting of cellulose acetate, toluenesulphonamide-aldehyde resin, a plasticizer (e.g., triacetin, diphenylolpropane, methylxylenesulphonamide and ethyltoluenesulphonamide) and a solvent.

A lacquer or coating composition is obtained when the mixture of cellulose derivatives and sulphonamide-aldehyde resins is dissolved in a vehicle which contains, in addition to the ordinary solvents, a glycol ether or one of its derivatives.<sup>31</sup>

Kollek<sup>32</sup> made lacquers by mixing aliphatic vinyl condensation products with sulphonamide-aldehyde resins. For instance, a clear, glass-like lacquer is formed by mixing benzenesulphonamide-formaldehyde resin with polymerized vinyl acetate (see Chapter 51). A coating material prepared by Gardner<sup>33</sup> consists of toluenesulphonamide-formaldehyde resin mixed with a natural resin or ester gum, and with chlorinated biphenyls (see Chapter 56). This mixture is incorporated with either nitrocellulose or drying oils.

A fusible coating composition is made by melting together soluble cellulose bodies and a gelatinizing agent such as p-toluenesulphonamide, or cresol derivatives.<sup>34</sup> The coats are applied to surfaces by painting, dipping, etc. A polish for surfaces lacquered with sulphonamide-aldehyde resin and cellulose preparations is made by mixing together an abrasive (tripoli), a diluent (benzene) and a softening agent (an aromatic sulphonamide).<sup>35</sup>

#### SHATTERPROOF GLASS

It is well known that shatterproof glass is made by placing between sheets of glass a layer of a cellulose ester, coated with an adhesive. One of the chief difficulties encountered in making such a product was to find a satisfactory adhesive which would be compatible with the cellulose ester and which would not be affected by light.<sup>36</sup> Gelatin, dextrin and natural gums were first utilized but they tended to discolor and become less transparent through the action of ultraviolet rays.

Gardner<sup>37</sup> noted that p-toluenesulphonamide resin, either alone or mixed with cellulose esters, possesses great resistance to decomposition by ultraviolet radiation and transmits relatively high percentages of light. He therefore proposed to use it for making laminated glass. A solution of the resin in toluene is applied to clean glass plates and, after a brief drying, the surfaces are pressed together. Also, a cement may be used, consisting of nitrocellulose (25 parts), butyl acetate (75 parts), p-toluenesulphonamide resin (50 parts) and toluene (50 parts). Other cellulose esters and ethers were suggested, and also viscose or celluloid.

<sup>35</sup> British P. 352,547, 1930, to British Celanese, Ltd.; *Brit. Chem. Abs. B*, 1931, 895.

<sup>36</sup> For a discussion of safety-glass plastics see *Plastic Products*, 1934, 10, 131.

<sup>37</sup> H. A. Gardner, U. S. P. 1,762,513, June 10, 1930; *Chem. Abs.*, 1930, 24, 3873. British P. 332,234, 1929; *Brit. Chem. Abs. B*, 1930, 906. Canadian P. 302,911, 1930; *Chem. Abs.*, 1930, 24, 4910.

Moss<sup>33</sup> used a film of toluene- or ethyltoluenesulphonamide-aldehyde resin as an adhesive to bind sheets of cellulose acetate to sheets of glass in the endeavor to make a shatterproof glass. Similarly a film of benzenesulphonamide-aldehyde resin has been used by Dreyfus.<sup>30</sup> The reinforcing layer for laminated glass may consist of a cellulose ester mixed with triacetin and applied with sulphonamide-aldehyde resin as a binder.<sup>40</sup>

An intermediate layer for safety glass which does not become brittle at low temperatures is made by mixing together toluenesulphonamide-formaldehyde resin and the polymerization products of acrylic acid or its derivatives.<sup>41</sup>

Ford and McCarroll<sup>42</sup> suggested a number of substances as adhesives for the celluloid layer in safety glass, for example: cellulose nitrate, formaldehyde-toluene-sulphonamide resin, camphor and tricresyl phosphate, vinyl acetate, formaldehyde-toluenesulphonamide resin and dibutyl phthalate, and other cellulose esters, resins, and plasticizers.

Fragile articles (glass or ceramic) may be reinforced by applying to them an external coating (0.005-0.03 inch thick) of toluenesulphonamide-aldehyde resin, either alone, or mixed with other resins and with cellulose esters or ethers.<sup>43</sup>

### PLASTICS

Sulphonamides were perhaps first used by Schmidt<sup>44</sup> to plasticize cellulose esters. Nitrocellulose was mixed with p-toluenesulphonamide to form films and to act as a substitute for camphor in making celluloid. Lindsay<sup>45</sup> made a plastic product by incorporating various sulphonamides and triphenyl phosphate with acetylcellulose in acetone solution, adding methyl alcohol, and allowing the mixture to gelatinize.

A study of sulphonamide derivatives as plasticizers for acetyl cellulose was made by Carswell.<sup>46</sup> Experiments were performed on retentivity, light-fastness, tensile strength and weather-resistance of the plastic mixtures of eight different aryl sulphonamide derivatives with the acetyl cellulose. The p-toluene methylene sulphonamide (a resinous substance made by condensing p-toluenesulphonamide with formaldehyde) proved superior to any of the sulphonamides not combined with formaldehyde. See Table 34. Bender<sup>47</sup> reported that this same substance was of value in plasticizing phenol-formaldehyde resins.

Dreyfus<sup>48</sup> mixed sulphonamides with cellulose esters and ethers for making pressed or molded articles, e.g., phonograph records or electric insulators. A blend of powdered cellulose acetate (100 parts) and p-toluenesulphonamide (45-55 parts) is melted and run into sheets, which are then ground to powder and incorporated with a filling material (180-200 parts), e.g., lampblack, ferric oxide or barium sulphate. This composition is kneaded on hot rolls and then pressed or molded

Benzene methyl sulphonamide . . . . .	100+	630	453	320	80	Poor
Benzene ethyl sulphonamide . . . . .	100+	724	414	290	115	Fair
p-Toluene methyl sulphonamide . . . . .	40	1140	460			Failed
p-Toluene ethyl sulphonamide . . . . .	40	1534	380	360		Poor
Xylene methyl sulphonamide . . . . .	100	532	475	350	350	Failed
p-Toluenesulphonanilide . . . . .	70	39	335	383		Poor
p-Toluene methylene sulphon- amide . . . . .	200	About 2000	660	408	349	Good
No plasticizer . . . . .	...	.	335			...

<sup>a</sup> Retentivity is defined as the per cent of plasticizer which can be incorporated in acetyl cellulose without "frosting."

<sup>b</sup> Light-fastness is expressed as the time of exposure of a 0.4 mm film in the Fade-O-Meter before the appearance of a slight discoloration.

into desired shapes. Dreyfus, Cameron and Schneider<sup>49</sup> made a similar plastic mixture with cellulose acetate, p-toluenesulphonamide, p-toluenesulphonimide, diethyl phthalate and rosin. A plastic material for phonograph records used by Rutstein<sup>50</sup> consists of cellulose acetate plasticized with an alkyltoluenesulphonamide and triphenyl phosphate together with shellac, cotton flock and fillers.

Moss<sup>51</sup> prepared a molding composition from cellulose acetate (30 parts), toluenesulphonamide-aldehyde resin (45 parts), vinyl acetate resin (100 parts), diethyl phthalate (10 parts), acetone (400 parts), benzene (100 parts), ethyl acetate (100 parts) and dioxane (100 parts). Moss and White<sup>52</sup> found that diphenylol propane, mono-methylxylene-sulphonamide, ethyl toluenesulphonamide and triacetin are good plasticizers for mixtures of cellulose acetate and toluenesulphonamide-aldehyde resins. Among other plasticizers which have been suggested are N-alkyl sulphonamides of o-dichlorobenzene.<sup>52a</sup>

Plastics made of cellulose derivatives and sulphonamide-aldehyde resins can be improved, according to Bren,<sup>53</sup> by incorporating urea (see Chapter 32), thiourea, or guanidine. The plastic material comprises a cellulose derivative, a sulphonamide-aldehyde resin (from 10 to 150 per cent of the amount of cellulose derivative) and a urea (8-50% of the equivalent of aldehydes present).

A transparent plastic material has been made by Walsh<sup>54</sup> by adding plasticizers to a toluenesulphonamide-aldehyde resin melting below 100°C. but above room temperature. With added pigments the composition can be used for making imita-

tion food articles. Walsh and Caprio<sup>55</sup> have made preparations consisting of a cellulose ester and a plasticizer (e.g., triphenyl phosphate), employing toluenesulphonamide-aldehyde resins (4-20 per cent of the weight of plasticizer) to prevent the exudation of the softener.

Sulphonamide-aldehyde resin may be used as a binder for inorganic compounds. For instance very durable marble objects can be made by fusing the resin with twice its weight of powdered marble and molding the mixture into any desired shape.<sup>56</sup>

#### OTHER USES

Toluenesulphonamide-aldehyde resins were employed by Gardner to deluster artificial silk so that it will more nearly resemble natural silk.<sup>57</sup> The resin is mixed in with the cellulose spinning-solution, and as the filaments form, the resin penetrates the filaments, rendering them opalescent. By using condensed aldehydes in addition to the resin, a much stronger filament is formed without sacrifice of softness. A typical spinning-solution consists of nitrocellulose (100 parts), p-toluenesulphonamide-formaldehyde resin (3 parts), paraformaldehyde (1 part), ether (200 parts) and alcohol (200 parts).

For the formation of threads from alkaline cellulose solution about 5 per cent (based on the weight of cellulose) of p-toluenesulphonamide-formaldehyde resin is dissolved in caustic soda and mixed intimately with the basic cellulose.<sup>58</sup> Threads and yarns produced from this mixture are said to have greater resistance to water than have ordinary viscose threads. If the viscose solution is to be made into films, from 10 to 20 per cent of resin is added. The films then possess improved electric resistance and water-repellent qualities. Thus ordinary cellophane is improved in resistance to ingress of moisture from air by the presence of this resin. These special films are useful for wrapping pipes to prevent corrosion, or as an insulating wrapping for telephone cables. In cases where the cloudy effect produced by the resin is undesirable it may be removed by passing the film over hot rolls.

In place of incorporating the alkaline resin solution in the cellulose, the transparent films from the latter can be coated with the liquid, dried and washed to remove the alkali. This same treatment is adaptable for waterproofing paper, wood and concrete. A composition containing 100 parts of toluenesulphonamide resin, 8 parts of sodium hydroxide and 92 parts of water has proved satisfactory. Addition of barium sulphate or similar pigments is recommended for the preparation of a cold water paint.<sup>59</sup>

Gardner has also increased the electrical resistance of films of regenerated cellulose by applying to their surfaces coatings of sulphonamide-aldehyde resin and cellulose esters.<sup>60</sup> In insulating tests an ordinary regenerated cellulose film 0.87 mil in thickness had a volume resistivity of 125 megohm-inches. The same film coated on each side with a resin-cellulose ester composition so that the total thickness was 1.52 mils had a volume resistivity of 1,500,000 megohm-inches. The coating used in this case consisted of cellulose acetate (5 parts), toluenesulphonamide-formaldehyde resin (5 parts), ethyl lactate (25 parts) and acetone (65 parts).

Lahousse<sup>61</sup> used p-toluenesulphonamide to decrease the viscosity of metallic

resinates for the impregnation of fibrous bodies to form insulating material. As an example, 10 kg. of p-toluenesulphonamide is heated to 150°C., 90 kg. rosin added and the temperature raised to 170°C. Zinc oxide is then introduced in small amounts and the temperature further increased to 185-190°C. Paper condensers and other articles are submerged in the molten mixture for 4-5 hours at 150-200°C. After cooling to 120°C., the impregnated object is removed.

Dreyfus and others<sup>32</sup> produced artificial bristles, horsehair or straw from solutions of cellulose esters and synthetic or natural resins. For instance, a thorough mixture of cellulose acetate (33.7 parts), toluenesulphonamide-formaldehyde resin (2.1 parts), acetone (54.6 parts) and water (9.6 parts) is spun into a drying atmosphere at 55-87°C. p-Toluenesulphonamide-formaldehyde resin was used by Seel<sup>33</sup> to coat the rear side of photographic films to render them non-static. A mixture of o- and p-toluenesulphonamide-formaldehyde resins has been employed by Wedger<sup>34</sup> as a softening agent in a cellulose acetate cement for uniting shoe parts.

#### MISCELLANEOUS REACTIONS OF SULPHONAMIDES

The reactions noted here do not involve sulphonamide-aldehyde condensations but they are included to suggest other possible sources of resins from sulphonamides or their derivatives.

A product useful as a plasticizing agent has been prepared by Carswell and Gump<sup>35</sup> by the action of an acetylating agent on a sulphonamide derivative. Acetyl chloride or acetic anhydride acts on an aryl sulphonamide in which one of the free hydrogen atoms attached directly to the nitrogen atom is replaced by a hydrocarbon residue. In studies on the action of benzenediazonium chloride on p-toluenesulphonamide in a cold alkaline solution, Key and Dutt<sup>36</sup> found that the reaction proceeded very slowly, producing a brownish red resinous mass soluble in most organic solvents.

In their investigation of benzenesulphonylguanidines, Clarke and Gillespie<sup>37</sup> found that arginine reacts with benzenesulphonylchloride in sodium hydroxide solution, forming a gummy mass (dibenzenesulphonylarginine). Esterification of this material with butyl alcohol produced a colorless resin.

Aromatic sulphonylchlorides were employed by Pfister<sup>38</sup> to esterify gum accroides (see Chapter 38). The natural gum, as it occurs, is highly acid in character, whereas the resin produced by esterification is neutral, and can be used in varnishes. The resin from gum accroides and p-toluenesulphonylchloride is a tough mass which can be dried and powdered, and is soluble in benzene and in butyl acetate. Melamid<sup>39</sup> obtained resins of high melting point by the reaction of aromatic sulphonylchlorides on soft pitch or anthracene oil. For instance, soft coal-tar pitch (100 parts) is heated with sufficient aqueous soda to neutralize acidity and then cooled. A benzene solution of p-toluenesulphonylchloride is added, and the mixture is stirred for 12 hours. The benzene solution is then separated from the aqueous layer, washed with water until neutral, dried over calcium chloride

and vacuum-distilled, leaving the resin as a residue. Analogous resins are obtained from the action of aromatic sulphonylchlorides on the salts of resinic, humic, or lignoceric acids.

Attempts to dibrominate 2-p-toluene-sulphonamidobiphenyl resulted in the formation of gummy masses containing 3,5-dibromo-2-aminobiphenyl in experiments performed by Bell.<sup>70</sup> Much tarry material was formed when Orndorff and Shapiro<sup>71</sup> attempted to utilize dehydrating agents such as sulphuric acid or stannous chloride to increase the yield of hydroquinolsulphonephthalein from the action of o-sulphobenzoic anhydride and hydroquinol. Phillips<sup>72</sup> obtained some black, tarry material as a by-product in making ethyl p-toluenesulphinate from p-toluenesulphiny chloride and ethyl alcohol, and in making 2-octyl-p-toluenesulphinate from p-toluenesulphiny chloride and *l*-2-octanol.

## Chapter 35

### Miscellaneous Nitrogen-Containing Resins

#### Nitro Resins

Although resinous bodies are frequently encountered in the nitration of organic substances, not many of them have been adequately described, and very few have appeared to find commercial application. Some of these resins possess unattractive colors and odors and many are unstable, decomposing (in some cases rather violently) when heated. In addition to nitro resins, materials of a resinous nature from various aliphatic and aromatic nitrogen compounds and from heterocyclic compounds are also considered in this chapter.

#### RESINS PRODUCED DURING NITRATION OF HYDROCARBONS

Schaarschmidt and Raack<sup>1</sup> obtained resinous material when attempting to nitrate benzene with a mixture of nitrosyl chloride and aluminum chloride at 60-80°C. The yield of resin at 80°C. was 10 times that at 60°C. An explanation proposed for the reaction is that a complex,  $2\text{AlCl}_3 \cdot 3\text{C}_6\text{H}_6 \cdot 3\text{NOCl}$ , is formed, which decomposes to hydrochloric acid, nitrosobenzene and aluminum chloride, the nitrosobenzene then reacting with benzene to form resins. Xylene and mesitylene yield resinous material when treated with nitrogen tetroxide at room temperature.<sup>2</sup> A mixture of 80 g. of m-xylene and 23 g. of dry nitrogen tetroxide was allowed to stand for 15 days. A thick oily layer slowly settled out. This viscous mass was steam distilled, yielding 14 g. of a dark resin. Similar treatment of 70 g. of mesitylene with 7.6 g. of nitrogen tetroxide gave 4.5 g. of a dark brown, brittle substance.

In the nitration of durene (1,2,4,5-tetramethylbenzene) in chloroform solution, Smith and Dobrovolsky<sup>3</sup> observed that unless the chloroform solution is neutralized as soon as possible after nitration, considerable amounts of red tar are formed. Herzenberg and Ruhemann<sup>4</sup> obtained from brown-coal tar a homologue of naphthalene (presumably 1,4- or 2,4-methyl isopropyl naphthalene) which, when heated for several days under reflux with dilute nitric acid, was converted into a viscous oil, solidifying to a resinous mass when cooled.

Stilbene is readily attacked by nitrogen pentoxide, forming sticky, brown plastic masses.<sup>5</sup> Likewise, tarry products result from the action of oxides of nitrogen on phenanthrene.<sup>6</sup> 6-Acetyltetralin when treated with nitric acid yields crude acetyl nitrotetralin, a dark brown resin.<sup>7</sup> Resinous or tarry materials have been formed in the nitration of o-nitrotoluene-p-sulphonyl-p-anisidine,<sup>8</sup> 4-p-toluenesulphon-

<sup>8</sup> F. Reverdin, *Helv. Chim. Acta*, 1924, 7, 567; *Chem. Abs.*, 1924, 18, 2142.

methylamidobiphenyl<sup>9</sup> and ethyl-bis-(4-aminophenyl)-methane hydrochloride<sup>10</sup> and in the nitrosation of 3,5-dichlorodimethylaniline.<sup>11</sup> In the nitration of m-aldehydophenyl carbonate to 4-nitro-3-aldehydophenyl carbonate, Mason<sup>12</sup> obtained tarry products. Attempts to nitrate p-cresol with nitrogen peroxide have produced resinous material.<sup>13</sup>

The nitration of triphenylcarbinol and of triphenylacetone nitrile yields amorphous, tar-like nitro derivatives.<sup>14</sup> Resinous products are also formed by the nitration of 4,4'-diethylureidobiphenyl.<sup>15</sup> Trimethylolethylmethane trinitrate,  $C_8H_6C(CH_3)_3(ONO_2)_3$ , is a waxy compound melting at 48°C. and is explosive in nature. These properties have suggested the use of the substance as a coating material for explosives, protecting them from moisture and at the same time increasing their sensitiveness.<sup>16</sup>

In the experiments of Fittig<sup>17</sup> the addition of acetone in small portions to fuming nitric acid yielded a yellow, viscid explosive oil exhibiting the properties of a nitro compound. Hydrogen sulphide and ammonium sulphide decomposed the compound, forming brown tarry liquids. The nitration of mesityl oxide yielded a brown, tough resin soluble in alcohol. One of the products of the action of nitrosyl chloride on acetone is a yellow oil (possibly phorone dinitrosochloride) which resinifies easily.<sup>18</sup>

Treatment of 3-4-dichloroacetophenone with a mixture of fuming nitric and concentrated sulphuric acids at 15°C. has resulted in resinous material.<sup>19</sup> Gummy products are obtained in the nitration of benzoin unless the conditions are carefully regulated.<sup>20</sup> Phenylcyclohexanone when treated with ethyl nitrite and potassium ethylate in ethyl alcohol at 0°C. formed a yellow oil.<sup>21</sup> Ether extraction of this oil left a residual orange-red liquid which, when slightly acidified with sulphuric acid, yielded a yellow wax. The ether extract of the yellow oil (mentioned above) gives on evaporation and further extraction a vitreous mass. Various glassy materials resulted on similar treatment of phenylcyclohexanone with nitrous vapors obtained by the action of nitric acid on arsenious oxide.

In the nitration of methyl cinnamylidenemalonate, a yellow solid was formed which decomposed to a semi-solid gum when placed over phosphorus pentoxide.<sup>22</sup> Nitric acid caused the resinification of diterpenes, obtained by Ikeda<sup>23</sup> from borneol by treatment with zinc chloride in benzene; and tarry material resulted when d-neomenthylamine was treated with nitrous acid.<sup>24</sup> The oxidation of anethole (p-propenylanisole) with nitric acid and mercuric nitrate in acetic acid solution produced anisaldehyde, anisic acid and a resinous substance<sup>25</sup> (35 per cent).

Nitro compounds frequently form resins when oxidized. The tar obtained on oxidizing o-nitrobenzylmalonate<sup>26</sup> with potassium permanganate and the formation of complex amorphous substances in the oxidation of m-dinitro- and sym-trinitrobenzene<sup>27</sup> with mercuric oxide are examples. Likewise, the reduction of

<sup>27</sup> H. H. Hodgson and E. W. Smith, *J.C.S.*, 1930, 2035.

nitration products often leads to resins and tars. For instance, resinous material has been obtained in the reduction of m-dinitrobenzene,<sup>33</sup> 2,4'-dinitrobiphenyl<sup>34</sup> and the nitration products of acetylene.<sup>35</sup> In the reduction of nitrobenzaldehyde thioether to the corresponding amino compound, an insoluble by-product is obtained. The aminobenzaldehyde thioether itself resinifies on standing.<sup>31</sup>

Resinous substances have been formed by the action of alcoholic potash on 6-nitro-7-methyl-2,4-bistrichloromethylbenzodioxin<sup>36</sup> and on crude methyl-m-nitrobenzylmalonate.<sup>37</sup> Alcoholic ammonia splits off hydrogen cyanide from o-nitrocinnamylglycolyl nitrile,  $O_2NC_6H_4CH=CHCH(OH)CN$ , and the rest of the molecule resinifies.<sup>38</sup>

#### CONDENSATIONS OF NITRO COMPOUNDS

In contact with potassium bicarbonate, 1-nitro-1-propene polymerizes to a yellow-brown solid soluble in acetic acid and in caustic soda.<sup>39</sup> 1-Nitro-1-butyne on exposure to the air is converted into a resinous mass.<sup>40</sup> Extensive resinification takes place when nitro derivatives of stilbene are exposed to ultraviolet light.<sup>41</sup> Similarly, resinous material has been reported from ultraviolet-light- or sunlight-exposure of nitropiperonal,<sup>42</sup> an alcohol solution of 3-chloro-4-nitrosophenol<sup>43</sup> and a chloroform solution of p-methoxy cinnamylidene-m-nitroacetophenone.<sup>44</sup>

Nitro derivatives have sometimes been condensed with aldehydes to form resinous substances. For instance, in the presence of piperidine, 4,6-dinitro-m-xylene condenses with salicyl-, bromosalicyl- and p-dinitroamino-benzaldehyde.<sup>45</sup>

Resins have been produced in the author's laboratory by condensing technical p-nitrochlorobenzene (m.p. 81-82°C.) with aldehydes. Acid reducing agents were found to be the best catalysts. Paraformaldehyde and p-nitrochlorobenzene, boiled for ten minutes with alcoholic hydrochloric acid and metallic zinc, give a dark, fusible resin (97 per cent yield) which is still fusible after 12 hours heating. If aqueous hydrochloric acid is employed instead of the alcoholic solution no resinification occurs. However, the aqueous solution permits resinification when furfural is used in place of paraformaldehyde. In this case the dark resin obtained is soluble but not fusible.

An aqueous solution of ammonium chloride, substituted for the hydrochloric acid, can be used successfully with paraformaldehyde. A rubbery mass is formed when equal parts of p-nitrochlorobenzene, paraformaldehyde and zinc dust are refluxed for one hour in an aqueous ammonium chloride solution. Heating this mass on a hot plate converts it into a dark, infusible resin. The production of the resin is accelerated by the addition of hexamethylenetetramine. In fact, the latter itself will condense with p-nitrochlorobenzene. Hexamethylenetetramine (25 parts) in aqueous solution refluxed with p-nitrochlorobenzene (50 parts) for 1 hour produced a dark, fusible body (70 parts). Heating on a hot plate changed

this to an infusible product soluble in water, alcohol and alcohol-benzene mixture (yield 35 per cent of original p-nitrochlorobenzene).

According to Korczynski<sup>42</sup> the resin-formation occurring in the condensation of di- or trinitrophenol with diphenylcarbamide chloride is a result of the photo-sensitiveness of the product. A trace of pyridine will cause otherwise stable p-nitrophenylcarbimide to polymerize in dry ether or benzene.<sup>43</sup>

Liquid mixtures of trinitrocresol (m.p. 101°C.) with other nitro compounds when cooled form eutectics as plastic masses.<sup>44</sup> Resinification of a mixture of trinitrocresol and trinitrotoluene occurs when 30-50 per cent of trinitrotoluene is used. When equimolecular proportions of p-nitroaniline and mercaptobenzothiazole are fused, or are heated together in alcoholic solution, a resinous product is formed which has been proposed as a feeble accelerator in rubber vulcanization.<sup>45</sup> For the same purpose, a resinous mixture of di-o-tolylguanidine, 2-mercaptobenzothiazole and phthalic anhydride in stearic acid or acetone solution has been suggested.<sup>46</sup>

Bogert and Stull<sup>47</sup> obtained a yellow gummy material from the interaction of zinc-o-aminoselenophenolate and o-nitrobenzoyl chloride in acetic acid solution, the gum apparently containing zinc in chemical combination.

Considerable resin is formed in the preparation of o-nitrodiphenylarsinic acid from o-nitrodiazobenzene chloride and phenylarsinic oxide in alkaline solution.<sup>48</sup> 10-Ethyl-9-nitroso-9,10-dihydrophenarsazine is described as a thick oil which solidifies to a tough mass. Alkaline solutions of the 10-ethyl and 10-methyl derivatives deposit red resinous masses when allowed to stand.<sup>49</sup> Partial resinification occurs when 2-nitro-6-methyldiphenylamine-6'-arsinic acid is dissolved in alcohol and hydrochloric acid and reduced with sulphur dioxide.<sup>50</sup>

Pernitrosoketocineole when treated with concentrated sulphuric acid at -15°C. yielded a light yellow, unstable solid, C<sub>10</sub>H<sub>14</sub>O (1-acetyl-3-isopropylidene-1-cyclopentene), which was converted into a sticky, brown pitch on exposure to air.<sup>51</sup>

Gummy deposits have been found at times in the mains and meters carrying coke-oven gas or similar gases.<sup>52</sup> Berkhoff<sup>53</sup> has found that such gums contain up to 8 per cent nitrogen and are insoluble in most organic solvents, but soluble in alkali, reprecipitating in acid solution. In the opinion of Berkhoff these resins are polymerization or condensation products of isonitrosites and nitrosates formed by gas-phase reactions between nitrogen peroxide<sup>54</sup> and unsaturated hydrocarbons such as styrene, indene and cyclopentadiene. (See Chapters 5, 9 and 11.)

Investigations of gas-main vapor-phase gum have been made by Jordan, Ward and Fulweiler.<sup>55</sup> The material is described as a dark brown, amorphous powder aggregated into lumps of various sizes. It contains an average of 4-7 per cent nitrogen and 22-32 per cent oxygen. The gum is unstable to heat, decomposing

mally present in the gas) catalyze the oxidation of nitric oxide to nitrogen peroxide.<sup>52</sup>

#### NITRO RESINS FROM PETROLEUM

A nitro resin has been obtained by Edeleanu and Filiti<sup>53</sup> through the nitration of petroleum oil or petroleum distillate (sp. gr. 0.870-0.890). One part of petroleum distillate is run slowly into 3 parts of a well-stirred concentrated acid mixture (5 parts of sulphuric to 1 part of nitric). Unchanged oil is skimmed off and the nitro resin is precipitated by addition of water to the acid solution. It was stated that the product can be used in varnishes and lacquers, as a substitute for camphor in celluloid and as a constituent of explosives when mixed with oxidizing agents. Heating with alkalis converts the resin into a dyestuff.<sup>54</sup> In the writer's laboratory, a dark brown to black resin has been obtained by passing oxides of nitrogen into the highly unsaturated light distillate obtained in the manufacture of Blau gas.

According to Charbonneau,<sup>55</sup> treatment of California petroleum oil with 5-10 per cent of concentrated nitric acid produces various tars and resins. One of them, a brown sticky resin, can be dissolved (1-3 parts) in crude alcohol (100 parts) to form a liquid fuel said to be superior to alcohol alone.

<sup>52</sup> To prevent gum-formation it is suggested that the best method is to remove the nitric oxide. See W. H. Fulweiler, *Gas J.*, 1934, 207, 253; *Chem. Abs.*, 1934, 28, 6277. K. <sup>55</sup> E. A. Charbonneau, U. S. P. 1,450,272, Jan. 8, 1924; *Chem. Abs.*, 1924, 18, 825.

One of the few real attempts to use nitro resins was made by Forrest and Meigs.<sup>60</sup> Petroleum distillates, or distillates from native solid bitumens (particularly gilsonite) are nitrated to form resinous products. The distillates from the destructive distillation of gilsonite are best because of their high content of unsaturated material.

Dilute nitric acid (sp. gr. 1.42) is added slowly in small portions while the oil is stirred. Since the reaction is exothermic and quite violent, no more than 1 part of acid to 2500 parts of oil is added at any one time, and the temperature must be kept below 104°C. The reaction is continued until the amount of acid added equals half the amount of oil. The nitro resin is precipitated either by cooling the reaction mixture to 10-24°C. or by running it into cold water. The substance resulting after washing free of acid is light yellow in color, soluble in alcohols and ketones but insoluble in water, dilute mineral acids, petroleum ether and carbon disulphide. The properties of the product vary with the fraction of distillate used. The fraction 65-204°C. produces a viscous oil resembling nitrated castor oil, that from 200-316°C. a light yellow, semi-solid resin, and that from 316-370°C. a hard, solid body. The resins can be mixed with pyroxylin to form lacquers, leather dressings and artificial leather.

Another nitro resin of this type has been made by Day.<sup>61</sup> Powdered gilsonite, grahamite or albertite is dissolved in nitric acid. After the light surface oil has been removed, the acid is diluted with water to precipitate the resin. A solution of the resin in alcohol, ether, benzene or maphtha can be used as a coating composition. A varnish suggested for metals<sup>62</sup> consists of coal tar (75 per cent), benzene (18 per cent) and nitric acid (7 per cent).

Tar has been converted into briquette-binding material in a process devised by Vivian.<sup>63</sup> The tar is heated to about 87°C. and then treated with 5-8 per cent of sulphuric acid and subsequently with 2-3 per cent of nitric acid. When the action of the acids has ceased, paraffin oil is added to reduce the viscosity. The mixture is then cooled, causing the formation of two layers, one consisting of light oils and the other of the heavy binding material. The light oils are removed for subsequent treatment, and the binding-material remaining is freed from acids by washing with water and alkali and is then run into molds to harden. Other uses suggested for the product include the making of road-paving blocks and electrical insulating material.

According to Flexer,<sup>64</sup> a mixture of kerosene and wood tar when nitrated yields a resinous product which can be used in paints and in plastic moldings and can be vulcanized with sulphur to form a rubber substitute. Plastic masses have been made by Reif<sup>65</sup> by mixing fibrous materials with a binder produced by the action of nitric acid on tars and oils.

#### NITROLIGNIN

Fischer and Tropsch<sup>66</sup> prepared nitrolignin by treating 150 g. of lignin<sup>67</sup> with 1 liter of nitric acid (5 N).<sup>68</sup> The solution was first cooled, and then warmed

until an orange color appeared. Subsequent filtration, washing and air-drying produced the nitrolignin as a soft, yellow powder (60 per cent yield). Analysis indicated the composition  $C_{20}H_{17}O_{10}N_3$  (containing 3 methoxyl and 6 hydroxyl groups). Attempts to reduce nitrolignin with tin and hydrochloric acid resulted in extensive polymerization, yielding a brown amorphous product insoluble in most solvents.

#### NITRATION OF NATURAL RESINS

Resinous material for use in varnishes has been obtained by Fry<sup>66</sup> by nitrating rosin or oil of turpentine. The resins have been termed "Oxycolophones" and "Oxyturpentines," since they are actually oxidation products formed in the process by decomposition of the nitrated substances. Notwithstanding this fact, the resins are mentioned in this chapter because, primarily, the procedure involves nitration.

Nitric acid (10-30 parts, sp. gr. 1.42) is added slowly to powdered rosin (100 parts), the mixture being kneaded to facilitate the reaction and to avoid the formation of lumps. Impure nitrocolophony, an olive-green powder, is obtained by this treatment. Decomposition of the nitrocolophony is accomplished by fusing it in a porcelain container heated by boiling water, resulting finally in a yellow resin. In the nitration and decomposition stages care must be taken because of the explosive character of the nitrocolophony. It is not advisable to work with large batches, since the reaction is exothermic.

Venice turpentine, or a mixture of oil of turpentine (1 part) and rosin (2 parts), is nitrated similarly to form resins. If a soft resin is desired, 10 parts of nitric acid are used for each 100 parts of the turpentine mixture, whereas 30-35 parts of nitric acid are used if a hard product is to be formed. The soft resin is superior to the hard variety in solubility in boiled oil or in oil of turpentine.

Rosin is more easily nitrated than Venice turpentine and the latter more easily than oil of turpentine. Consequently, in the nitration of rosin-turpentine mixtures, the nature of the final product is affected by the time of reaction. To restrict the nitration chiefly to the rosin, the acid is allowed to act only two hours. In this short time the oil of turpentine is not greatly attacked, several days of treatment being required to convert it into a satisfactory resin. The nitration of a solution of rosin in a drying oil produces an alcohol-soluble resin. By heating "Oxycolophones" for several hours at 100-204°C. orange or red tints are developed, making bases for staining-varnishes.

Nitrated colophony has been used directly in varnishes,<sup>67</sup> and other nitrated resins either alone or with oils have been employed in varnishes containing cellulose esters and bitumens.<sup>68</sup> Other suggested uses for nitrated resins of this type include the making of dyestuffs<sup>69</sup> and fixatives for printing inks.<sup>70</sup> The fact that rosin is sometimes selectively nitrated has been used by Donath to detect its presence as an adulterant.<sup>71</sup>

## NITRO-RESINIC ACIDS

One of the principal constituents of rosin is abietic acid. (See Chapter 37.) In various investigations on the constitution of this acid, nitro derivatives have been formed.<sup>70</sup> In following up the work of earlier investigators, Dubourg<sup>71</sup> obtained crystalline di- and trinitro derivatives, and in addition some resinous products. Abietic acid (20 g.) in an inert solvent, e.g., carbon tetrachloride (200 cc.), when treated with concentrated nitric acid (100 cc.) yielded a yellow-gray, viscous mass. An explosive, amorphous body was produced when water was added to a solution of abietic acid in concentrated nitric acid.

In further studies of the action of nitric acid on abietic acid<sup>72</sup> there were obtained two principal products, one a crystalline dinitro derivative, and the other a yellow, amorphous mass containing nitrogen (decomposes above 100°C.). The yellow mass was found to be readily soluble in alkalies, the solutions absorbing oxygen avidly from the air. Attempts to esterify the sodium salt with alkyl sulphates yielded tarry material.

Amorphous or resinous substances containing nitrogen have been obtained by the action of nitric acid on other resinic acids such as  $\alpha$ -elemic acid,<sup>73</sup>  $C_{27}H_{44}O_6$  (from *Canarium commune*), copal acid,<sup>74</sup>  $C_{28}H_{46}O_6$  (from Congo copal), and tsugic acid,<sup>75</sup>  $C_{18}H_{22}O_7$  (from *Tsuga sieboldii*, Carr).

## RESINS FROM ALIPHATIC NITROGEN COMPOUNDS

Certain of the cyanamides have yielded resinous products in various investigations. For instance acetyl cyanamide and isovaleryl cyanamide have been described as syrup-like compounds which explode when heated, forming amorphous solids.<sup>76</sup> Madelung and Kern<sup>77</sup> found that dicyanamide very readily forms an amorphous polymer of high molecular weight. It is, of course, well known that cyanogen compounds yield cyclic trimers and that cyanogen itself will polymerize. Likewise, hydrogen cyanide forms a trimer in alkaline solution,<sup>78</sup> the reaction producing at the same time a brown, humus-like body, known as azulmic acid,  $C_4H_2N_4O$ . The simple ketene imines,  $H_2C=C=N-R$ , e.g., ketene ethylimine, being very unsaturated, polymerize rapidly at room temperature.<sup>79</sup> It is reported that on long standing  $\alpha,\alpha'$ -tetraethyldiaminoadipic acid solidifies to a glassy hygroscopic material.<sup>80</sup>

In their work on the tetraethylammonium radical, Schlubach and Ballauf<sup>81</sup> obtained a deep blue solution by the electrolysis of tetraethylammonium iodide. It was found that the addition of 2,6-dimethyl-1,4-pyrrone to the solution colored it yellow, and on subsequent evaporation a brown, resinous mass was formed. The electrolysis of potassium alkyl amidines in liquid ammonia to synthesize hydrocarbons has been found to result in resinous deposits on the anode.<sup>82</sup>

Fusion of such proteins as casein, fibrin, elastin and keratin with phthalic anhydride at 200°C. has yielded amorphous products of high molecular weight.<sup>98</sup> A hard and semi-transparent body results from the reaction of soya-bean protein (extracted with methyl alcohol) with formaldehyde.<sup>99</sup> Adhesive and plastic products are obtained by the action of acetaldehyde on casein.<sup>100</sup> A transparent, colloidal mass resistant to solvent action has been obtained by condensing the gases evolved when gelatin (3 parts) is heated with wood creosote (4 parts) at 160-250°C. The material is recommended as a preservative composition for paintings.<sup>91</sup>

#### RESINS FROM AROMATIC AMINES

Aniline when mixed with water and exposed to strong sunlight produces resinous substances soluble in sulphuric acid. This effect is attributed to the development of oxidation products intermediate between aniline and nitrobenzene.<sup>92</sup> In the electrochemical oxidation of asym-m-xyldine to hydroxyxylolquinone, the use of a platinum anode instead of a litharge one leads to the formation of much resinous matter.<sup>93</sup>

König and Buchheim<sup>94</sup> report that the condensation of o-toluidine with bromo- or chloroacetal formed a liquid (b.p. 225-230°C.) which on treatment with nitrous acid yielded small amounts of easily resinifying bodies. Methylene diphenyldiamine and phenol yield a semi-solid resin when heated together in nearly equal proportions.<sup>95</sup> The addition of paraformaldehyde (7-10 per cent) hardens the material somewhat. One of the uses suggested for the resin is the impregnation of brake linings; in this case it is baked into the lining material at 400°C. The condensation of resorcinol with 2,7-N-diacetyldiaminodiphenic anhydride, using zinc chloride at 110°C., is reported to form a red glassy mass.<sup>96</sup>

Alkylene or arylene diamines when heated with naphthols yield naphthalene-substituted diamines, useful as antioxidants in rubber.<sup>97</sup> Thus, for example,  $\beta$ -naphthol reacts with ethylenediamine or with m-phenylenediamine. This is but one example of the many instances of the employment of weak bases as antioxidants for rubber. For this purpose resins prepared by condensing a polyhydroxy aliphatic amino compound (e.g., triethanolamine) with a substance containing an imino grouping, e.g., phenyl- $\alpha$ -naphthylamine have been utilized.<sup>98</sup>

Resinous material is obtained when diphenylamine is heated with d-glutamic acid at 240°C.<sup>99</sup> Also in the manufacture of diphenylamine, tarry compounds are formed.<sup>100</sup> The distillation of 2-2'-diaminodiphenylbutane with hydrochloric or sulphuric acid results in a 40 per cent yield of p-isobutenylaniline. The latter compound after standing 4 days and then being heated for 1 day at 100°C. was converted (25 per cent yield) into a dark-red hard glass.<sup>101</sup>

Heating dianilinothiourea,  $C_6H_5-NH-NH-CS-NH-NH-C_6H_5$ , with hydrochloric acid for 30 minutes at  $30^\circ C$ . and then for 1 hour at  $60-65^\circ C$ . out of contact with air, yielded diaminodiphenylthiourea,  $NH_2-C_6H_4-NH-CS-NH-C_6H_4-NH_2$ . Black, tarry products resulted in attempts to isolate the free base or its hydrochloride, disulphide or metallic derivatives.<sup>102</sup>

Bromination of phenylisoamylthiocarbamide in chloroform solution gives an orange-red resin. Similar treatment of sym-phenylisobutylthiocarbamide results in a red gum which becomes crystalline on standing and resinous when in contact with diethyl ether or petroleum ether.<sup>103</sup>

The pyrolysis of allylaniline, diallylaniline and diallyl-p-phenetidine at  $275-300^\circ C$ . yielded in each case the parent primary amine, gaseous hydrocarbons (mainly propylene) and considerable resinous material.<sup>104</sup> If 1-phenyl-4-anilino-butadiene is distilled, a red, rosin-like solid is formed.<sup>105</sup> The main product of the thermal decomposition of malonanilide,  $CH_3(CONHC_6H_5)_2$ , is a dark brown, brittle mass.<sup>106</sup> This same resinous material results when aniline and ethyl malonate are heated together. Dark red to brown-black resins are developed on warming  $\beta$ -2,4-dinitrophenylhydroxylamine or its benzoate or acetate.<sup>107</sup>

Vorländer and co-workers<sup>108</sup> have found that the acetyl derivative of tri-p-aminotriphenylacetoneitrile and the condensation product of the latter with anisaldehyde are both amorphous substances. When phenylmethylacetoneitrile is added to a mixture of sodium ethoxide solution and ethyl cyanoacetate, there is formed ethyl  $\alpha$ -cyano- $\beta$ -imino- $\alpha$ -phenylvalerate. This compound, when treated with sulphuric acid, yields ethyl 2,4-diamino-1-methylnaphthalene-3-carboxylate, which changes very readily into a black, resinous mass.<sup>109</sup>

Scheibler and Baumgarten<sup>110</sup> report that ethyl N- $\alpha$ -cyanopiperonylaminoacetate,  $CH_3O_2C=C_6H_4-CH(CN)-NH-CH_2-CO_2C_2H_5$ , is a viscous liquid, which may be converted by the action of alcoholic potash into 3,4-methylenedioxybenzylideneglycine, a pale brown, viscous syrup which solidifies to a glass-like resin. In the benzoylation of trans-phenylserine,  $C_6H_5-CHOH-CHNH_2-COOH$ , there resulted a small amount of a colorless by-product, which when heated at  $160^\circ C$ . was changed into a yellow resin.<sup>111</sup>

#### DIAZONIUM RESINS

The aromatic diazo compounds contain the group  $-N=N-$ . They are of interest because of their great activity and because they constitute the starting point in the preparation of many dyestuffs. The reactivity of these compounds has often led to the formation of resinous material.

The instability of diazonium hydroxides in aqueous solutions was noted by Hantzsch,<sup>112</sup> who found that, even in the cold, decomposition takes place with the formation of a large amount of diazo resin. This reaction was studied further by Angeli and Jolles.<sup>113</sup> Aniline was diazotized in the usual manner and then the solution was made alkaline with potassium hydroxide and allowed to stand

for 7 days until no more nitrogen was evolved. The principal reaction product was a diazo resin (70 per cent yield).

The work was continued by Jolles,<sup>124</sup> studies being made on the resinifying action of alkaline solutions of the diazonium compounds of aniline, o- and p-anisidine, m- and p-toluidine, p-phenetidine, o- and p-aminobenzoic acid and  $\alpha$ -naphthylamine, by allowing their solutions in alkali to stand. Yields of 70-93 per cent were obtained together with traces of the corresponding hydrocarbons. It was supposed that the resinification is caused by the oxidation of one diazotate by another. From the nitrogen content of the resin, Jolles suggested that the diazotized aniline reacts as follows:

The presence of the  $-N=N-$  grouping in the resin is assumed from the fact that aniline is formed when the resin is reduced with tin and hydrochloric acid; and when the resin is oxidized one of the products is benzoic acid. Resins identical with that from diazotized aniline are obtained from phenylazoxycarboxamide and from nitrosoacetanilide on prolonged treatment with alkali.

Hellerman and co-workers<sup>125</sup> have found that  $\beta,\beta'$ -diphenyldiazoethane,  $(C_6H_5)_2CHCH(N_2)$ , can be kept below  $-10^\circ C$ . for several hours without decomposition, but at  $0^\circ C$ . or higher it loses some of its nitrogen and changes to a yellow, resinous mass.

The diazotization of p-nitroaniline sometimes produces resinous substances. For instance, gummy materials have been formed in certain cases when nitrogen tetroxide was used as the diazotizing agent.<sup>126</sup> A considerable amount of a brown resin was obtained when p-nitroaniline was diazotized and then coupled with isosafrole.<sup>127</sup>

Busch and Schöffner<sup>128</sup> found that when aniline is diazotized in hydrochloric acid solution, rendered alkaline and poured into an aqueous solution of potassium nitromethane, a brown-red resinous mass is precipitated, a further quantity being thrown down from the supernatant liquid by carbon dioxide.

Attempts made by Bischler and Brodsky<sup>129</sup> to reduce p-nitrobenzenediazonium chloride to p-nitrophenylhydrazine, using stannous chloride, yielded resinous material. Purgotti<sup>130</sup> tried to accomplish this same reduction using sodium bisulphite. Although some p-nitrophenylhydrazine was formed, the major product was a resinous mass. The experiments of Purgotti were repeated and confirmed by Davies.<sup>131</sup> It was found that the resin formation can be prevented almost completely by using sodium sulphite in neutral or alkaline solution, giving a good yield (80 per cent) of p-nitrophenylhydrazine. If the solution is allowed to acidify, there is obtained an orange-red precipitate of sodium p-nitrodiazobenzene sulphonate, which readily decomposes to form a resin.

In converting 5-aminosalicylic acid into the corresponding thiocyanogen derivative by use of the Sandmeyer reaction, resinification occurs when a temperature higher than  $65^\circ C$ . is employed.<sup>132</sup> The pyrolysis of diazoamino-p-toluene at  $150-170^\circ C$ . yields considerable resinous material of a basic nature.<sup>133</sup> Methyl and ethyl p-azoxycinnamate yield on hydrolysis p-azoxycinnamic acid as a yellow,

amorphous solid insoluble in the common organic solvents but soluble in alkali.<sup>124</sup>

#### RESINS FROM HYDRAZINE AND RELATED SUBSTANCES

The hydrazines, hydrazones, alkazines and hydrazides are to be considered together because of their similarity in structure, all of them having the =N—N= linkage.

The addition of phenylhydrazine to an alcoholic solution of chloroacetophenone mixed with an aqueous solution of sodium acetate produced a resinous mass when the mixture was heated to 40°C. and stirred.<sup>125</sup> Similarly resinous products have been obtained from a mixture of phenylhydrazine and 2-ethyl-1-hydrindone heated at 130°C. for 7 hours.<sup>126</sup> In studies of the action of cyclohexyl bromide on arylhydrazines it was found that the reaction of  $\alpha$ -naphthylhydrazine with cyclohexylbromide resulted in resin formation.<sup>127</sup> Dimethylpyrone reacts with hydrazine hydrate to form a viscous, almost colorless liquid. Heated at 240°C. under 10 mm. pressure, the liquid becomes a faint-yellow glass-like mass. On further heating, ammonia is split off and a hard, bright-yellow substance,  $C_{14}H_{17}N_8$ , results.<sup>128</sup>

A semi-transparent gel is formed by heating anhydrous hydrazine with cellulose in a closed bomb tube. On opening the tube, ammonia is evolved and the residue turns to a green glassy substance as it is dried over sulphuric acid.<sup>129</sup>

It was noted by Ottolino<sup>130</sup> that the interaction of phenylhydrazine hydrochloride (2 mols) and benzaldehyde (3 mols) produces a dark green, friable resin (40 per cent yield). When the condensation is carried out in the presence of arsenic acid, the resin is harder and a higher yield is obtained (60 per cent).

Previous experiments by Ciusa and Ottolino<sup>131</sup> showed that this resin also results on heating zinc chloride with phenylhydrazine and benzaldehyde. The suggested formula for the product is

In these experiments an intense green resin of the same type was formed by the action of dry hydrogen chloride or of hot concentrated hydrochloric acid on hot alcoholic solutions of aromatic arylhydrazones.

The resinifying action of zinc chloride on hydrazones was mentioned by Minunni,<sup>132</sup> who found this tendency was a difficulty to be overcome in his synthesis of pyrazolecarboxylic acids by the interaction of aldehyde hydrazones and acetoacetic ester in the presence of zinc chloride.

Studies on the thermal decomposition of azines, principally aldazines and ketazines, were made by Howard and Hilbert.<sup>133</sup> The pyrolysis of benzaldazine at 290–310°C. yielded as a residue a hard brown resin (82 per cent yield), from which some crystalline substances were obtained by ether extraction. Resinous materials were obtained also in the pyrolysis of anisaldazine, p-tolualdazine, benzophenoneketazine and acetophenoneketazine.

<sup>133</sup> L. B. Howard and G. E. Hilbert, *J.A.C.S.*, 1933, 54, 2622.

The hydrazides of aromatic carboxylic acids are usually prepared from the esters of these acids by the action of hydrazine hydrate. Alexa and Gheorghiu<sup>124</sup> found that, with some acid anhydrides, hydrazine hydrate forms dihydrazides, but that in the case of succinic, glutaric and maleic acid anhydrides, non-crystalline gums are developed.

Witte<sup>125</sup> has prepared hydrazides of nitrobenzenesulphonic acids by the action of hydrazine hydrate on the corresponding sulphonyl chlorides. Some of the preparations resulted in crystalline compounds, but in the case of sym-2,2'-dinitro-dibenzenesulphonhydrazide resinous products were formed.

Curtius and Moll<sup>126</sup> report that the dihydrazide of o-carboxyphenoxyacetic acid when heated with methyl, ethyl or benzyl alcohol is converted into an impure diurethan. A resinous product results when the diurethan is hydrolyzed by hydrochloric acid. Resins were obtained by Bertho and Hölder<sup>127</sup> by heating, in ethyl or methyl alcohol, the dihydrazide of 1-p-xylyl-1,2,3-triazole-4,5-dicarboxylic acid.

Oxidation of the dihydrazide of diphenic acid with potassium ferricyanide in ether and ammonium hydroxide yielded the monohydrazide and some resinous aldehydic matter.<sup>128</sup>

### PIRAZOLES AND INDAZOLES

In the pyrazole group are included all compounds with the skeleton ring containing 3 carbon and 2 nitrogen atoms. Pyrazole, pyrazoline and indazole have the following structures:

Indazoles are related to the pyrazoles, their ring system consisting of a condensed benzene-pyrazole nucleus.

One of the methods of preparing pyrazolines consists in reacting unsaturated ketones with hydrazines. Auwers and Kreuder<sup>129</sup> found that 1-phenyl-3-isobutenyl-5,5-dimethylpyrazoline (from phorone and phenylhydrazine) forms a dark brown resin in contact with the air. When 1-nitroso-5-phenylpyrazoline is heated with mineral acids the nitroso group is split off and a resinous product is formed.<sup>140</sup>

Auwers and Strödter<sup>141</sup> found that 3-p-anisylindazole changes to a resinous mass when distilled at 205°C. under 10 mm. pressure. They noted also that the esters of indazole-1-carboxylic acid when heated lose carbon dioxide, forming amorphous products and small amounts of 1- and 2-alkylindazoles. Attempts made to replace the hydroxyl hydrogen of 2-hydroxy-3-phenylindazole by the acetyl, benzoyl or methoxyl group produced resinous substances.<sup>142</sup>

Auwers and Mauss<sup>143</sup> prepared N-methyl-N-benzimidazolium iodide from ben-

zylimidazol and methyl iodide. The product was converted into a resin when heated at 250-270°C.

#### NITROGEN-CONTAINING ALDEHYDES AND KETONES

The nitro-substituted ketones and aldehydes have been discussed in a previous section of this chapter. Rojahn and Seitz<sup>144</sup> found that the 3- and 5-pyrazolealdehydes are oily liquids resembling aromatic aldehydes in general reactions. However, in the Cannizzaro reaction there are formed only traces of the corresponding carboxylic acids, the major product consisting of resinous bodies.

In experiments conducted by Freri<sup>145</sup> the action of fuming nitric acid on acetylene produced  $\alpha,\beta$ -di-isoxazole ketone to which was assigned the structure

Mixtures of this ketone with benzene and with toluene formed pitchy masses if exposed to sunlight.

The reaction of benzoyl cyanide with resorcinol in cold dry ether, in the presence of zinc chloride and hydrogen chloride, yields a tough, red-brown resin.<sup>146</sup> Boiling acids decompose 4-hydroxy-1-azidoacetylbenzene,  $N_3-CH_2-CO-C_6H_4OH$ , forming green resinous products.<sup>147</sup>

#### RESINS FROM PYRIDINE

Resinous products have been derived from both the reduction and oxidation of pyridine and its derivatives. A considerable amount of resinous matter was obtained in the oxidation of pyridine with dibenzoyl peroxide.<sup>148</sup> Shaw<sup>149</sup> noted that if 95 per cent alcohol is used with sodium in place of absolute alcohol, the reduction of pyridine by Ladenburg's method<sup>150</sup> yields no piperidine, but ammonia is evolved and the main product is a brown, non-nitrogenous resin. The dehydrogenation of pyridine through the agency of anhydrous metallic salts, e.g., ferric chloride<sup>151</sup> or cobaltic chloride,<sup>152</sup> results in the formation of resins.<sup>153</sup>

Emmert and Werb<sup>154</sup> prepared a colorless, crystalline compound, 1,2,4,6-1',2',4',6'-octamethyltetrahydro-4,4'-bipyridyl, by methiodination and subsequent reduction of 2,4,6-trimethylpyridine. It was found that this compound rapidly resinified when exposed to the atmosphere. In alcoholic solution it decolorized iodine with the formation of an amorphous mass. Treatment of diisoamylpyridylum

iodide solution with silver oxide and subsequent hydrogen-reduction of the filtrate at 95°C. leads to the formation of a black resin.<sup>155</sup>

Amorphous products were obtained in the reduction of 2-phenyl-5-benzoylpyridine with amalgamated zinc and hydrochloric acid.<sup>156</sup> It has also been noted that 2-methyl-5-acetylpyridine reacted with ethyl formate and sodium ethylate to form the sodium salt of 2-methyl-5-(hydroxymethyleneacetyl)pyridine. Subsequent treatment of this salt with sulphuric acid and copper sulphate resulted in a yellow oil (presumably the free ketone) which resinsified on exposure to air.

The reduction of 2-methyl-6-phenyleinchomeronic acid (5 g.) with sodium amalgam (75 g., 2.5%) yielded  $\alpha$ -benzoylmethyl- $\gamma$ -valerolactone as an exceedingly viscous oil.<sup>157</sup> When twice as much sodium amalgam was used the product obtained was  $\alpha$ -( $\beta$ -hydroxypropyl)- $\gamma$ -phenyl- $\gamma$ -butyrolactone as a yellow, semi-solid, glassy mass. The barium salt of this acid is glass-like and brittle.

When methyl-2-diphenyl-4,6-pyridinephenylimine is heated in alcoholic solution, rearrangement occurs forming o-aminobenzyl-2-diphenyl-4,6-pyridine.<sup>158</sup> Resinous substances result when this is treated with concentrated hydrochloric acid, and also when treated with methyl iodide.

Scholtz<sup>159</sup> reports that p-xylenedipiperidide reacts with m-xylene bromide in chloroform to give a mixture of  $\alpha$ - and  $\beta$ -m-xylene-p-xylenedipiperidinium dibromides. The same result is obtained when m-xylenedipiperidide reacts with p-xylene bromide. Whereas Scholtz described both bromides as crystalline substances, Meisenheimer and his co-workers<sup>160</sup> in repeating this work found that although the  $\beta$ -bromide is crystalline, the  $\alpha$ -bromide is obtained either as an amorphous powder or as a glassy mass.

Pyrollopyridine derivatives, or indolizines, were prepared by Chichibabin<sup>161</sup> by the reaction between  $\alpha$ -halogen aldehydes and ketones and  $\alpha$ -alkylpyridines. With quinaldine the resulting benzo-indolizines were obtained as resins, presumably polymers of the indolizines. Quinaldine and dibenzoylperoxide reacted to form dibenzoylquinaldine and a resinous substance. Also, the halogen addition product of indolizine was changed to an oily base in potassium hydroxide solution, this oily body oxidizing to a red resin in the air. Le Fevre<sup>162</sup> has obtained gummy products in the reaction of piperidine with 6-nitropiperonal and with 2,7-dibromo-4,6-dinitroxanthene.

Attempts made by Vorländer and his associates<sup>163</sup> to methylate or ethylate p-hydroxyphenylpyridone led to the formation of tars. N-phenyl- $\gamma$ -chloropyridinium chloride (obtained from N-phenylpyridone and thionyl chloride) forms a brown resin in cold sodium hydroxide solution. When p-nitrobenzylpyridinium halides are treated with sodium hypobromite, p-nitrobenzoic acid is obtained. The use of benzylpyridinium halides (without the nitro group) leads to resins practically insoluble in alkali.<sup>164</sup>

Chichibabin<sup>165</sup> noted that the reaction between phenacyl bromide and  $\alpha$ -aminopyridine produced the hydrobromide of 2-phenylpyrimidazole and of another base, N,N'-diphenacyl- $\alpha$ -pyridone imide. The hydrochloride of this latter compound is a colorless, viscous resin. Almost equal weights of phenacyl bromide

and phenyl pyrimidazole when melted together produce a transparent, nearly colorless resin, easily soluble in water. At 100°C.  $\alpha$ -picoline reacts with alkali iridohexachlorides to form crystalline trichloro-tri- $\alpha$ -picolino-iridite. The reaction at 50°C., however, yields resinous products.<sup>166</sup>

#### RESINS FROM QUINOLINE

The reduction of quinoline with sodium amalgam (25 per cent sodium) yields a small amount of biquinoline and a large amount of a yellow, resinous base.<sup>167</sup> Resinous products were obtained by Conolly<sup>168</sup> from the action of sodium on 6-methylquinoline, 7-methylquinoline and 8-methylquinoline, respectively.

Studies on the Beyer synthesis<sup>169</sup> of quinoline derivatives have been made by Roberts and Turner.<sup>170</sup> Their method consists essentially in the reaction of substituted anilines with a mixture of paraldehyde, acetone and hydrogen chloride in nitrobenzene. Resinous or tarry materials were obtained in attempts to condense the following: 2,4,5-trichloroaniline, p-nitraniline, 3-chloro-6-nitraniline and 3,4-dichloro-6-nitraniline. Tars were also secured in some of the efforts at reduction and diazotization of the quinoline derivatives.

When quinoline is heated at its boiling point with barium oxide there is formed some carbostyryl and a large amount of a dark, thick resin.<sup>171</sup> Condensation of quinoline with epichlorohydrin in sodium hydroxide yields a dark red, semi-oily mass which solidifies in a dry atmosphere.<sup>172</sup> Extraction of this mass with alcohol removes a small amount of a red compound,  $C_{10}H_{12}N_2$ , and leaves resinous material. The action of acetic anhydride on 2-phenyl-4-aminoquinoline also yields a resin-like mass.<sup>173</sup>

The yellow picrate of 1-methyl-2-isobutyl-1,2-dihydroquinoline easily changes into a mixture of resinous material and a red picrate.<sup>174</sup> Considerable resin is also formed in the conversion of 2-isobutylquinoline into its picrate. When 1-methyl-2-phenyl-1,2-dihydroquinoline is heated at 250°C. in an inert atmosphere a resinous polymer is formed.

Resinous products have been obtained from isoquinoline derivatives by Haworth, Perkin and Rankin,<sup>175</sup> by Child and Pyman<sup>176</sup> and by Gulland and Virden.<sup>177</sup>

Certain oxyaminoquinolines used as pharmaceutical products have been described as yellow oils which solidify to glassy masses. Among these are 6-methoxy- and 6-ethoxy-8-aminoquinoline<sup>178</sup> and 8-(2-dimethylaminocyclohexylamino)-6-methoxyquinoline.<sup>179</sup>

The oxidation of p-aminophenol with silver oxide yields quinone monoimine.<sup>180</sup> The quinone imines tend to polymerize, especially in the presence of acids, though the presence of alkyl groups in the nucleus lessens this tendency.<sup>181</sup>

## RESINS FROM PYRROLE

Pyrrole,  $C_4H_5N$ , is similar in structure to pyridine but is much less stable. It dissolves slowly in dilute acids but is rapidly resinified in concentrated mineral acids. The addition of alkali to dilute hydrochloric acid solutions of pyrrole and its derivatives does not regenerate the original bases but causes resin formation. The substances obtained are polymers of pyrrole and its derivatives.<sup>182</sup> Although concentrated hydrochloric acid resinifies pyrrole, the introduction of dry hydrogen chloride into an ether solution of pyrrole causes no resinification,<sup>183</sup> but forms the hydrochloride of tripyrrole,  $(C_4H_5N)_3 \cdot HCl$ .

Pyrrole can be converted into tripyrrole by dissolving 25 cc. in 100 cc. of hydrochloric acid (20 per cent), diluting the solution with 500 cc. of cold water and adding ammonia slowly until no more precipitate forms.<sup>184</sup> The tripyrrole is recovered from this amorphous precipitate by ether extraction. This trimer is unstable and is soon transformed into a higher polymer (m.p.  $121^\circ C$ .) which is not soluble in ether. If tripyrrole is heated to  $100^\circ C$ ., ammonia is evolved and a bright brown, glassy mass results. If this mass is further heated to  $300^\circ C$ . it breaks down into indole and pyrrole. Ammonia is also evolved from dilute acid solutions of pyrrole when they are heated, leaving an amorphous, red powder known as pyrrole red.

The analysis of tripyrrole by Tronov and Popov<sup>185</sup> indicates the formula  $C_{12}H_{17}N_3O$ . These workers stated that tripyrrole has never been isolated as the oxygen-free base. In their experiments the action of alkalies or of ammonium hydroxide on the hydrochloride of tripyrrole caused the formation of the pyrrole red,  $C_{12}H_{14}N_3O$ , mentioned above. Tripyrrole has been obtained from pyrrole by the condensing action of ethylene glycol and of glycerol.<sup>186</sup>

The oxidation of pyrrole and its derivatives yields syrupy mixtures which solidify to vitreous masses.<sup>187</sup> Considerable work has been performed by Freri<sup>188</sup> on the oxidation of pyrrole and tripyrrole with ozone. Depending on the conditions and the solvents used, resinous substances of various colors are formed in some cases, and in others the products resemble the pyrrole blacks obtained with other oxidizing agents.

A study of the pyrrole blacks has been made by Quilico,<sup>189</sup> who expressed the belief that all the blacks are formed by the condensation of oxypyrrole nuclei,  $(C_4NO)$ . Although pyrrole blacks are usually formed by oxidation, Illari<sup>190</sup> has obtained a compound of this type by condensation in a strongly reducing medium, through the action of formic acid on pyrrole. Black, amorphous condensation products of high molecular weight result<sup>191</sup> when either  $\alpha$ -dichloro- or  $\alpha$ -trichloroacetylpyrrole is boiled with aqueous potassium hydroxide (5 per cent solution).

Both 4-methyl-2-ethylpyrrole and pyrrole-N-carboxylic acid are unstable. The former resinifies in contact with the air<sup>192</sup> and the latter in dilute mineral acids.<sup>193</sup>

<sup>192</sup> H. Fischer and J. Klarer, *Ann.*, 1926, 447, 48; *Brit. Chem. Abs. A*, 1926, 412.

<sup>193</sup> W. Chelintsev and B. Mazorov, *Ber.*, 1927, 60, 197; *Chem. Abs.*, 1927, 21, 1648.

Feist<sup>194</sup> found from his experiments that pyrrole derivatives with more than 1 hydrogen atom in the ring will combine with aromatic aldehydes in molecular proportions. In most of the reactions of this type crystalline compounds were obtained, although resinous masses were formed in the reaction of 2,4-dimethylpyrrole with benzaldehyde and with p-nitrobenzaldehyde and of the ethyl ester of 4,6-dimethylpyrrole-3-carboxylic acid with cinnamic aldehyde and with salicylic aldehyde.

If acetaldehyde and pyrrole are heated together in a sealed tube the mixture is converted into a dark brown gum, perhaps a product of polymerization.<sup>195</sup> Tars are formed when pyrrole is condensed with some ketones such as methylethyl and phenylethyl ketones and 1- and 2-methylcyclohexanones.<sup>196</sup> Resins applicable in photography are formed by the reaction of five-membered mono-heterocyclic compounds (e.g., pyrrole) with methylethyl ketone, aniline or  $\alpha$ -naphthylamine.<sup>197</sup>

Pictet and Rilliet<sup>198</sup> noted that formaldehyde (40 per cent) and pyrrole react readily, yielding an insoluble, hard, red mass. If 4 per cent formaldehyde is used there is formed formaldehydopyrrole,  $C_4H_5ON_2$ , a white, insoluble compound which will not crystallize.

It was observed by Chelintzev and Maksorov<sup>199</sup> that pyrrole and formaldehyde (4 per cent), condensed with hydrochloric or sulphuric acid as a catalyst yield an amorphous, rose-colored polymer (m.p. 82-83°C.) containing a residue comprised of 6 to 8 of the following groupings:

When this polymer is heated to 140°C. and then cooled it forms a transparent, vitreous body.

Equimolecular proportions of pyrrolidine and formaldehyde (as trioxymethylene) when heated together in sealed tubes for 6 hours at 145-150°C. yield a homogeneous amorphous mass.<sup>200</sup> If this mass is dried with potassium hydroxide and distilled (at 30 mm.) a dark resinous residue is obtained. From the distillate two liquids, pyrrolidinomethyl alcohol and N,N'-dipyrrolidinomethane,

are recovered, the latter possessing a strong tendency to resinify.

If gaseous formaldehyde is passed into magnesylpyrrole in ether, and the mixture then heated on the water bath for 2 hours and subsequently decomposed with ice-cold aqueous ammonium chloride, resinous products are obtained.<sup>301</sup> Magnesylpyrrole, sulphur and benzoyl chloride have been found to form a black infusible, insoluble substance.<sup>302</sup>

Black pigments have been produced by Giua<sup>303</sup> from pyrrole and oxalyl chloride, (COCl)<sub>2</sub>. Pyrrole (6.4 g.) dissolved in absolute ethyl ether (100 cc.) at -6°C. is treated with oxalyl chloride (12 g.). The temperature is allowed to rise and the mixture is heated on the water bath. Hydrochloric acid is evolved in the reaction and a black pigment precipitates out. This pigment is infusible and amorphous, soluble in hot concentrated inorganic acids. Another brown infusible, insoluble pigment is formed when the liquid from the above reaction is evaporated to dryness and the residue extracted with ether and benzene.

Sanna and Chessa<sup>304</sup> prepared pyrrole- $\alpha$ -ketomethylcarbinol ethyl ether, C<sub>8</sub>H<sub>11</sub>NO<sub>3</sub>, by the action of ethylglycolyl chloride on magnesylpyrrole in anhydrous ethyl ether. The compound is a thick, brown liquid which forms with hydriodic acid a black, insoluble resin. Resinification of 3-carbethoxy-2,4-dimethylpyrrole-5, $\beta$ -acrylic acid,

occurs when it is treated with hydrogen bromide and glacial acetic acid.<sup>305</sup>

Robinson<sup>306</sup> reports that 2,3-(2'-phenylpyrrolo-4',5')-N-methyl-quinoline,

resinifies when heated above 100°C.

#### RESINS FROM INDOLE

Indole, C<sub>8</sub>H<sub>7</sub>N, or benzopyrrole, contains a benzene nucleus condensed with a pyrrole nucleus. It is a solid melting at 52°C.

and boiling with partial decomposition at 245°C. Like pyrrole it is easily resinified with hydrochloric acid.<sup>307</sup> The action of dry hydrogen chloride on a solution

of indole in benzene yields the colorless diindole hydrochloride<sup>200</sup> melting at 145-150°C. Free diindole has been obtained as an amorphous mass (m.p. 100-102°C.) by treating the hydrochloride with ammonium hydroxide.<sup>200</sup> Triindole has been formed by the action of metaphosphoric acid on indole,<sup>210</sup> and by the interaction of indole and diindole hydrochloride.<sup>211</sup> It has also been recovered from the residue of the distillation of indole.<sup>212</sup> Oddo<sup>213</sup> found that if a 10 per cent alcoholic solution of indole is exposed to air and sunlight for 2 months, a yellow compound,  $C_{16}H_{15}ON_3$ , is formed. If this compound is treated with hydrochloric acid it is converted into a resin.

Resinification occurs when 7-methylindole is treated with benzoylchloride and when 5- and 7-methylindoles are shaken with hydrochloric acid (5 per cent).<sup>214</sup> In benzene solution, 1- and 7-methylindoles polymerize when treated with hydrogen chloride, and although 3-methylindole (skatole) behaves similarly, 3-ethylindole does not.<sup>215</sup>

In the preparation of indole derivatives by the Grignard reaction, resinous substances often result. Indolylmagnesium iodide and ethyl acetate react to form 1-acetylindole which partly resinifies<sup>216</sup> when heated to 300-350°C. A small amount of pitch and a considerable amount of a red amorphous powder (insoluble in water and in ether) are formed when magnesylindole and phthalylchloride react in ether solution.<sup>217</sup> The ethyl ester of  $\beta$ -indoleglyoxylic acid (from magnesylindole and ethyl chloro-oxylate) reacts with benzene diazonium chloride to give an unstable compound which resinifies easily.<sup>218</sup> Magnesylmethylketole is oxidized by hydrogen peroxide to 3-hydroxy-2-methylindole (m.p. 40°C.) which quickly decomposes to a black, sticky mass.<sup>219</sup> Resinous bodies are formed in the preparation of  $\beta$ -indolylacetonitrile from indolylmagnesium iodide and chloroacetonitrile in cold anisole.<sup>220</sup>

Oxalyl chloride and 2-methylindole react to form crystalline 2-methyl-3-indoleglyoxyl chloride which when heated in neutral solvents yields a magenta-red resin.<sup>221</sup> Reduction of the oxime of 2-methylindole-3-aldehyde yields the corresponding amine. If hydrochloric acid is added to an ether solution of this amine, a resin precipitates out in 25 per cent yield.<sup>222</sup> An extensive study of the condensation of indole derivatives with aldehydes has been made by Burr,<sup>223</sup> in his investigations on humin formation. Resinous substances were obtained in many cases. Blount and Robinson<sup>224</sup> describe  $\beta$ -3-dihydroindolylpropionic acid as a pale, viscous oil, and its crude benzoyl derivative (formed by action of benzoyl chloride) as a gum.  $\gamma$ -3-Dihydroindolylbutyric acid and its benzoyl derivative are both resinous.

Isatin can be considered a derivative of indole because it is formed by the

oxidation of indigo blue and also by the oxidation of oxindole. Resins have resulted from the condensation of isatin with various ketones<sup>226</sup> such as furfurylidene-acetone, methylcinnamylvinyl ketone and benzalethyl ketone. Resinification of isatin and of N-methyl isatin occurs when they are used as catalysts in the dehydrogenation of amino acids.<sup>226</sup> Silver isatin and benzoyl chloride react in benzene or in ether to form isatoid (m.p. 178-182°C) which can be obtained in crystalline form only from acetic acid solution. When dissolved in any other solvent it is precipitated as an oil by the addition of water. Evaporation of these solutions yields brilliant reddish-yellow lac-like residues.<sup>227</sup>

#### RESINS FROM CARBAZOLE

Carbazole, or dibenzopyrrole,

is a stable compound melting at 238°C. It occurs in crude anthracene obtained from coal tar. Perkin and Tucker<sup>228</sup> found that when potassium permanganate is added to a hot solution of carbazole in acetone a vigorous oxidation reaction sets in, giving a small yield of crystalline isomeric bicarbazoles and a major yield of an amorphous substance (m.p. 175°C). This substance was investigated by McLintock and Tucker,<sup>229</sup> who found that treatment with hydriodic acid for 20 hours at 150°C. gave as the principal reduction product a substance identical with carbazole. There was also formed in the reduction a small amount of a cream-colored amorphous mass (m.p. 300-310°C.).

Resinous products are produced by the reaction between carbazole (or its derivatives) and olefins containing 3 or more carbon atoms.<sup>230</sup> The reaction is carried out under pressure in an inert solvent, using a contact agent such as aluminum chloride or fuller's earth. Soft resins are formed from propylene and carbazole and from propylene and N-ethylcarbazole, whereas from carbazole and cyclohexene a hard resin results. These bodies are presumed to be mono- or polyalkylated carbazoles. Pale, transparent resins can be obtained from such products by condensation with aldehydes using sulphuric or hydrochloric acid as the condensing agent.<sup>231</sup> Diisopropylcarbazole when condensed with formaldehyde yields a resin melting at 95°C. Sulphonation of the alkylated carbazoles produces materials which can be used to increase the wetting and emulsifying power of aqueous solutions.<sup>232</sup>

#### RESINS FROM ALKALOIDS

An attempt has been made here to classify some of the many resinous materials obtained from alkaloid derivatives. Because of the variety of reactions involved

only brief mention is made of the methods by which the resinous substances are obtained. The original work should be consulted for details. Resinous masses have been obtained from some of the derivatives of aporphine alkaloids<sup>233</sup> and from the methohalides of various derivatives of strychnidine,<sup>234</sup> brucidine<sup>235</sup> and neostrychnidine.<sup>236</sup> In efforts to synthesize alkaloids similar to protopine, resins were formed from the derivatives of homopiperonylic acid.<sup>237</sup> The derivatives of pseudoaconine and pseudoaconitine<sup>238</sup> and of sparteine<sup>239</sup> have yielded varnish-like materials in various reactions.

The following alkaloid derivatives have been described as resinous in character: neopine,<sup>240</sup> dibromoniquine,<sup>241</sup> tetrahydro-normethylmorphinethine,<sup>242</sup> and the hydrochloride of N-tryptamine (from calycanthine).<sup>243</sup> Certain alkaloid derivatives are sometimes obtained in crystalline or powdery form, but later resinify on air-exposure. Among these are quinotoxineoxime,<sup>244</sup> derivatives of quinineamine,<sup>245</sup> akuammine perchlorate,<sup>246</sup> and dihydrodesoxycinchonine.<sup>247</sup> Amorphous products have been obtained in the reduction of  $\alpha$ -chlorocodide (from codeine),<sup>248</sup> and in the oxidation of quebrachamine<sup>249</sup> and of hydroxyacanthine.<sup>250</sup>

If the hydrochloride of hydroxyacanthine is dissolved in dilute potassium hydroxide and then concentrated potassium hydroxide is added, the potassium salt separates as a resinous mass. The methyl ether of hydroxyacanthine is also resinous.<sup>251</sup> A gum is formed when protoberberinium chloride is heated in potassium hydroxide solution.<sup>252</sup> The hydrochloride of the methyl ester of lupinic acid (from lupinine) is converted into a resin by thionyl chloride.<sup>253</sup> Diversine produces resinous substances in its reaction with benzoic acid, phenylhydrazine, ethyl chloroformate and with bromine in glacial acetic acid.<sup>254</sup> Many of the alkaloid salts of the hydrogen phthalate of n-propylvinylcarbinol and of the hydrogen succinate of ethylvinylcarbinol are of a gummy nature.<sup>255</sup> Resinous or tarry products are formed when cocaine is heated with p-nitrobenzyl chloride or with saligenin.<sup>256</sup>

Amorphous substances have been formed in many cases in the condensation of aromatic aldehydes with  $\alpha$ -hydroxylepidine and with  $\gamma$ -hydroxyquinaldines.<sup>257</sup> Similarly, gummy materials have resulted from the condensation of formaldehyde with 1-benzyl-1,2,3,4-tetrahydro isoquinoline,<sup>258</sup> and of methylal with 1-homo-

## Chapter 36

### Resins from Wood and from Carbohydrates

The resins considered in this chapter are representative of some of the progress made in the utilization of waste products from wood and other plant materials. Because of undesirable properties possessed by many of them they have been used but little. The resins from carbohydrates, included at the end of the chapter, are probably of more interest than the others.

Wood consists principally of cellulose, lignin and sap, the latter containing resins and dissolved material. An extensive study of the composition of lignin has been made by Klason<sup>1</sup> who has found two principal constituents:  $\alpha$ -lignin,  $(C_{10}H_{10}O_4)_n$ , 64 per cent, and  $\beta$ -lignin,  $C_{10}H_{12}O_4(C_6H_7O_2COCH_3)_n$ , 36 per cent. The average lignin content of wood is about 26 per cent. Willstätter and Kalb<sup>2</sup> observed in their studies on lignin that boiling hydriodic acid and phosphorus convert it into a colorless, weakly acid resin, soluble in alcohol and acetic acid.

In the investigations of Legeler<sup>3</sup> it was noted that treatment of wood with phenol and small amounts of hydrochloric acid freed the wood from lignin but at the same time caused the formation of resins from the condensation of phenol and lignin. This reaction was also noticed by Jonas<sup>4</sup> who described the phenol-lignin as an amorphous, brown product.

Various resins have been produced by the action of phenols on lignin-containing materials, particularly wood. For instance, phenols and sawdust, using as catalyst either sulphuric or hydrochloric acid, yield a product resembling asphalt or pitch.<sup>5</sup> In the process of Hartmuth,<sup>6</sup> resinous materials for lacquers or adhesives are produced. Wood is heated with phenols either in concentrated form or diluted with water, alcohol or liquid hydrocarbons, the phenol combining with the lignin of the wood and leaving the cellulose unchanged. Catalysts include inorganic or organic acids and acid substances such as the chlorides of tin, zinc or aluminum and also ammonium chloride. The phenol-lignin compound contains free hydroxyl groups and can be methylated.<sup>7</sup>

The phenolic digestion of wood under pressure yields a resinous derivative of phenol and cellulose.<sup>8</sup> Wood flour is heated with 4 times its weight of phenol at 250°C. for from 2 to 20 hours depending on the product desired. Uncom-

<sup>7</sup> Y. I. Chulkov, I. A. Speranskaya and V. K. Kusnetsov, *Plast. Massui*, 1934 (2), 16; *Chem. Abs.*, 1934, 28, 6326.

<sup>8</sup> E. E. Notovny and C. J. Romieux, *U. S. P.* 1,731,315, July 16, 1929, to J. S. Stokes; *Chem. Abs.*, 1929, 23, 4357. See *Plastics*, 1930, 6, 149.

bined phenol is removed by distillation leaving behind a brownish-black resin of high melting point. If the period of heating is short, some of the wood remains undigested and can serve as a filler for molding. Modification of the product was effected by the addition of ammonia or various aldehydes. A small amount of sulphuric acid may be employed to accelerate reaction.<sup>9</sup>

A somewhat similar method was used by Prentiss<sup>10</sup> Wood, in finely divided form (100 parts), is digested with phenol (29 parts) in alkaline solution (12 parts ammonium hydroxide, sp. gr. 0.90, in 800 parts of water) for 4 hours under a pressure of 200-300 pounds per square inch. The reaction product is boiled for 1 hour under reflux after a solution of formaldehyde (29 parts in 43 parts of water) has been added. The solid material is then freed from liquids and molded into desired shapes using a pressure of 1000 pounds per square inch at 150°C. A composition for high-pressure molding is formed by the action of phenol (10 parts) on finely ground wood (100 parts) using hydrochloric acid (0.3 part) as a catalyst.<sup>11</sup>

Peanut hulls were utilized for resin production by Jones<sup>12</sup> who heated them with phenols and acid. A black sticky mass was formed, which was ground under water, boiled and washed to remove acidic substances. Barium carbonate<sup>13</sup> is also recommended to neutralize the mixture. The ground material, after drying, can be hot-molded. Wood shavings, oat and cottonseed hulls, corn cobs and cotton are other cellulosic materials that may be substituted. Use of an aldehyde hardening agent is reported to yield a highly resistant plastic substance.

Wood pulp from hemlock or spruce was disintegrated and treated with phenol or cresol by Lowen and Benson.<sup>14</sup> Hydrochloric acid was added and the whole mass heated 6 hours at 70°C., air-dried for several days and ground in a ball mill. The powder was then heated at about 80°C. to plasticize it, molded and finally baked at a rising temperature (up to 150°C.) till hard. Some results obtained by these investigators are given in Table 35.

TABLE 35.—Composition of Wood Pulp Plastics.

Pulp	Phenol	Cresol	Acid	Plasticizer	Remarks
g.	g.	g.	g.		
175	175	..	18	None	Hard, black solid
50	66	..	10	None	Similar to above
50	..	38	10	None	Hard but slightly brittle
50	..	25	10	None	Brittle
50	..	62.5	10	None	Hard, slightly brittle
50	..	75	10	None	Very plastic. Hard after baking
50	..	62.5	10	Castor oil	Strong and hard
50	..	62.5	10	Glycerol	Very strong

Lignin also has been condensed with aldehydes and amines to give resinous products. Black resins of various degrees of hardness and luster were obtained from lignin (from corn cobs) and aromatic amines, including aniline, o- and p-toluidine, benzidine and  $\alpha$ - and  $\beta$ -naphthylamine.<sup>15</sup> As a part of the same experimental work black resins were made from lignin and furfural, using as a catalyst either hydrochloric acid, calcium oxide, sodium carbonate or pyridine. Similarly, a molding composition is formed by heating furfural and hydrolyzed

A varnish of furfural and lignin in various solvents has also been made by I. Phillips (U. S. P. 1,890,526, Feb. 28, 1933; *Chem. Abs.*, 1933, 27, 3098).

wood with a mineral acid as catalyst.<sup>16</sup> Wood is hydrolyzed with steam (pressure 120 pounds per square inch) in the presence of 3 per cent sulphuric acid. The resulting fibrous material (100 parts) is acidified with hydrochloric acid (0.5 part), mixed with furfural (5 parts) and molded at 120°C. under a pressure of 2000 pounds per square inch. Within 15 minutes a hard resinous product is secured. If one part of an aromatic amine is added to the mixture before molding the water-resistant qualities are improved.

Fiberboard may be manufactured by treating cellulosic material in aqueous suspension with an agent (urea, phenols or aldehydes) capable of combining with the cellulose. By sheeting the fibrous mass, drying and subjecting to heat and pressure, hard boards are secured.<sup>17</sup>

In the method of Lauter<sup>18</sup> finely divided wood (sawdust) is acted on by an aldehyde, but reaction does not take place with the lignin of the wood but rather with the natural resins it contains. For this reason pine or spruce wood is used. The finely divided wood is moistened with formaldehyde or acetaldehyde and then molded at 115°C. under 1000 pounds pressure. Ushakov and Freidberg<sup>19</sup> prepared plastic materials from birch or fir sawdust by treatment with phenol before condensing with formaldehyde. Stein<sup>20</sup> condensed the nitro and acetyl derivatives of cellulose with phenols and aldehydes to prepare resins.

It may be of interest to note here certain methods of recovering the natural resin from resin-rich wood. If wood such as Swedish pine is heated under pressure with concentrated alkali and sodium chloride solution, it disintegrates, and the resins are converted into alkali salts.<sup>21</sup> Fatty acids and lignin are precipitated with the resin, but their properties are sufficiently related to those of the resin to have no harmful effect in its use. According to König,<sup>22</sup> if wood is heated under pressure with dilute mineral acids or dilute alkalies, a liquid is obtained from which resins can be precipitated by the addition of ammonium hydroxide or calcium carbonate.

The action of mineral esters of polyhydric alcohols on such substances as wood, straw or peat furnishes compositions said to be useful as coating or binding materials.<sup>23</sup> For instance, the residue from the saccharification of peat when heated with ethylene dichloride at 140°C. in an autoclave gave a solution which may be applied directly to wood or mixed with varnishes. Evaporation of the solution yielded asphaltic materials, but if water or a salt or alkaline solution is added a finely powdered pigment is formed. Residues from the saccharification of peat or wood may be converted also into plastic materials by mixing with sulphur, tars or pitch.<sup>24</sup> The coatings or molded articles produced in this way are reported to be resistant to acids.

A resin suggested as a substitute for natural resins (pitch, asphalt and lac) is made from wood, wood waste or grass<sup>25</sup> by heating with phenol to a sufficient

degree only to open up the fibers. The cellulose is separated and excess phenol removed from the residue.

Treatment of finely-divided wood with an alkylene oxide (at temperatures up to 180°C.) in the presence of a weak base or acid gave materials which may be molded into desired shapes.<sup>30</sup> Wood in pieces may be treated similarly, yielding a non-porous product said to be superior to the initial wood in mechanical properties. Insoluble plastic bodies are formed when cork meal is suspended in an inert medium such as chlorobenzene and esterified with acetic anhydride or phosphorus oxychloride in pyridine.<sup>31</sup>

The treatment of cellulose or other vegetable matter with a specific enzyme from latex yields a substance which may be polymerized or hardened by the action of an aldehyde or ketone in either alkaline or acid mediums. The resultant product<sup>32</sup> is reported to resemble rubber in its properties. A modification in the procedure involves maceration of the plant matter in sodium bisulphite and phenol solutions.<sup>33</sup>

Substances resembling horn in texture have been obtained by Schorger in studies on the gelatinization of lignocellulose.<sup>30</sup> Both hard and soft woods were gelatinized with dilute alkali and then flocculated with acetic acid. The mass was washed and dried at 30-40°C., yielding the horn-like material. A neutralized suspension of gelatinized aspen when spread on a smooth surface and allowed to dry at room temperature yielded a pale yellow, translucent film. A product resembling horn has also been formed from lichenin (from Iceland moss).<sup>34</sup> The pentanitrate was produced by the action of nitric and sulphuric acids and then gelatinized with a solvent.

According to Berl and Biebesheimer,<sup>35</sup> cotton treated with alkalis (e.g., N-caustic soda solution) at 310-330°C. under 180-200 atmospheres pressure is converted into carbon dioxide, hydrogen and a highly viscous material which on exposure to air became a black resinous mass, slightly soluble in alcohol and ether and very soluble in acetone. Hydrogenation of this mass at 420-460°C. yielded a liquid resembling petroleum.

Concentrated sulphurous acid reacts with lignocellulose to furnish soluble lignone derivatives. Oxidation of a solution of these derivatives with chromium oxide gives rise to insoluble gel-like materials.<sup>36</sup> If the gels are used to impregnate wood or fabrics they may be formed within the structure of the wood or fabric by controlling the temperature of the solution. To illustrate, a mixture of the lignone solution and chromic acid is made and immediately applied to wood. If the temperature is kept at about 16°C. gel formation will not occur for 24 hours. Viscous colloidal solutions have also been obtained by the action of triphenylchloromethane on cellulose or starch.<sup>34</sup>

Tanning compounds were obtained by Jaeger and Witzel<sup>37</sup> by the condensation of cellulose, phthalic anhydride or aldehydes, and aromatic hydrocarbon residues, using sulphuric acid as a catalyst. A lighter color may be secured by bleaching the product with chlorine or sodium hypochlorite.

## RESINS FROM WOOD DISTILLATION

Although the main constituents of pyroligneous acid are wood alcohol, acetic acid and tar there are also small amounts of aldehydes, ketones, amines and phenols. Methods of preparing phenol-aldehyde resins from pyroligneous acid were developed by Bardy and Duchemin.<sup>36</sup> One procedure consists in boiling tar-free pyroligneous acid under reflux for several hours, and another in heating phenolic oils with formaldehyde in hydrochloric acid.

The principal method is to pass pyroligneous acid vapors (freed from tar) into an absorption vessel containing alkali carbonates or milk of lime. In order to get the largest yield of resins, each absorption vessel is connected to a battery of retorts instead of to a single retort, because in such destructive distillation the bulk of aldehydic material is liberated before phenols. With a battery of retorts the phenolic vapors from the end of one distillation will meet the aldehyde vapors from the beginning of another. In each absorption vessel dark-colored liquids are formed which, when acidified, become yellow and then deposit a black resin (melting at 60-70°C.). The resin is soluble in alkalies and is reprecipitated by acids. It is also soluble in acetone, methyl alcohol and methyl acetate but the solubility is decreased by heating the resin to high temperatures. If it is heated to 200°C. and then cooled a hard, black mass of conchoidal fracture is obtained. Although the total yield of resin is only about 0.5% of the weight of wood used, the recovery of resin facilitates the purification of methyl alcohol and sodium acetate, which are the desired products from pyroligneous acid. Crude methyl alcohol gives a small amount of light-yellow resin when it is distilled over alkali. Resinous material is derived also from the mother-liquors of sodium acetate.

Resin formation in crude methyl alcohol by the action of alkalies was noticed also by Chute.<sup>37</sup> In his process of making wood alcohol the addition of excess alkali to a pyroligneous acid distillate resulted in the development of a yellow resin which (Chute suggested) could be used as a dyestuff since it imparted a bright-yellow color to organic material when properly applied.

Two kinds of tar are formed during the distillation of wood. As one is soluble in pyroligneous acid and the other is relatively insoluble they are distinguished by the terms "dissolved tar" and "settled tar." Hawley and Calderwood<sup>38</sup> have found through studies on tar from hard maple that dissolved tar contains a large proportion of phenolic and acidic constituents<sup>39</sup> and is sensitive to the decomposing or polymerizing action of heat at temperatures far below those at which portions of settled tar distil without decomposition.<sup>40</sup>

A molding resin has been made from the soluble tar of wood distillation by condensation with formaldehyde, trioxymethylene or hexamethylenetetramine.<sup>41</sup> A fraction of the tar taken between 195-250°C. is mixed with formaldehyde and heated under reflux for half an hour at 90-100°C. Then a small amount of ammonium hydroxide is added and heating is continued for 12 hours. In a typical example, 145 parts by weight of the tar fraction are used with 121 parts of formaldehyde (40 per cent solution) and ammonium hydroxide equivalent to 3 parts of ammonia. After 12 hours of heating a viscous oily layer is formed which is decanted from the aqueous mixture and heated for 2 hours in an open container at 170-180°C. The result is a

dark brown resin, hard and not melting but capable of softening when heated. It may be mixed with fillers and molded into articles said to possess strength and good electrical- and heat-insulating properties. The resin is unaffected by acids and alkalies and is partially soluble in benzene or solvent naphtha.

In another procedure, the tar from coniferous wood is saponified with concentrated alkali, separated from unsaponified material and then warmed with formaldehyde.<sup>46</sup> The viscous mass obtained is washed with water and well dried. The resulting resin is soluble in solvent naphtha, forming a paint said to give moisture-resistant coatings.

A resinous material for varnishes has been produced by the hardening action of lime on pine-tar fractions, freed from oily constituents.<sup>48</sup> For instance, light pine tar is distilled at 100-160°C. with superheated steam until oily constituents are no longer obtained in the distillate. About 20 per cent of the tar is thus converted into a light distillate containing turpentine oil and 70 per cent remains as a viscous residue. The addition of 5 per cent calcium hydroxide hardens this residue and it can then be dissolved in a solvent to give varnishes, light to dark brown in color. It is reported that these varnishes dry rapidly to a glossy, but not sticky, finish.

A modification of the above procedure consists in substituting acids for alkalies.<sup>44</sup> Wood tar or wood-tar oil is treated with concentrated sulphuric acid and the resulting water-soluble substances are removed. After separation of oily constituents by steam, air or solvents, the residue is soluble in alcohol or acetone and can be used for black varnishes or paints. Coatings of this material are stated to be waterproof and resistant to alkalies, benzene or lubricating oils.

If wood tar is heated and agitated with chlorine (either liquid, aqueous or nascent) a brittle black-brown resinous mass results.<sup>45</sup> A rapidly drying varnish giving a lustrous coating is obtained by dissolving the resin in alcohol.

Hamburger<sup>46</sup> prepared a resin by heating wood tar with zinc oxide (or oxides of other heavy metals) at 110°C. As much as 12 per cent of zinc oxide can be added without injuring the properties of this resin. A binder for artificial stone was made by Flexer<sup>47</sup> by oxidizing wood tar, treating the product with concentrated alkali and then digesting it with a thinning medium (dilute ammonium hydroxide or alcohol). The solid product is washed with water and pressed dry. It is then melted and mixed with 4 to 5 times its weight of sand or gravel and molded into desired shapes.

A balsam-like viscous liquid has been obtained by Pallas<sup>48</sup> from pyroligneous acid tar. The tar is washed several times with boiling water and then made alkaline with calcium hydroxide and saturated with sulphur dioxide. A clear liquid results, which on evaporation yields a viscous balsam substance intended for use as a salve base and in textile finishing.

#### RESINS FROM WOOD-PULP MANUFACTURE

Many attempts have been made to recover resinous material from waste liquors in both the soda and sulphite processes of making wood pulp. Schmid<sup>49</sup> stated

<sup>42</sup> German P. 338,854, 1919, to Chem. Fabr. Flörsheim H. Noerdlinger; *J.S.C.I.*, 1921, 40, 742A. See also K. A. Lingner, French P. 329,971, 1903; *J.S.C.I.*, 1903, 22, 104.

<sup>49</sup> W. Schmid, *Papier-Fabr.*, 1931, 29 (*Tech.-Wiss. Teil*), 1; *Chem. Abs.*, 1931, 25, 3165.

that the average yield of liquid rosin from alkali pulp waste liquors is 30 kg. per ton of pulp made, varying of course with the process and the type of wood used.

One method of extracting resins from liquors of the soda process was devised by Greenwood.<sup>50</sup> The alkaline liquor remaining after the digestion of wood is known as "black liquor," and contains all the non-cellulose constituents of the wood. Floating on the surface of the liquid is a foam known as "crude rosin soap," containing both saponified and unsaponifiable resins. The "soap" is brought into intimate contact with a solvent (petroleum ether, gasoline or naphtha) by emulsification. Upon the addition of a mineral acid, resin acids are released and dissolve in the solvent. The mixture is heated moderately, causing the solution of resin acids to float on top. This layer is treated with a second solvent (methyl alcohol) immiscible with the first. Abietic acid is selectively dissolved by the second solvent and the two layers are separated. Evaporation of the second solvent yields crystalline abietic acid which is converted into rosin by heating. The residue from recovery of the first solvent contains a less pure rosin.

A somewhat similar procedure was used by Bergström.<sup>51</sup> Resinates from the alkaline liquor are treated with sulphuric acid and then with turpentine oil (cold at first and then heated). A clear solution is formed which is distilled under vacuum to obtain resins. The black liquor from the alkaline digestion of esparto grass yields a coagulated resinous precipitate when treated with an excess of sulphuric acid.<sup>52</sup> The resin is insoluble in ether, oils and turpentine, but is soluble in acetic acid, acetone, phenol, alcohol, aniline and alkalies. Its use as a varnish and for sizing and waterproofing purposes has been suggested. Resin from black liquor can be mixed with fibrous material and small amounts of phenol resin and glue added to form a molding composition.<sup>53</sup>

French<sup>54</sup> recovered impure resin from alkaline liquors (used to digest resinous wood) by passing an acid gas, e.g., sulphur dioxide, into the liquor. A hydrocarbon solvent (benzene, toluene or gasoline) is used for purification by vacuum distillation. The precipitated resin may be converted into water-soluble resinates by treatment with sodium carbonate solution, followed by crystallization.<sup>55</sup>

Lange<sup>56</sup> obtained a binding agent for briquettes from the liquors produced by the action of sodium carbonate on finely-divided wood. A sludge containing resin-soap and lignin is deposited in the liquor when cooled. The soap is converted into large flocks by sodium hydroxide and then treated with sodium peroxide to oxidize the lignin. A binding agent is secured after the liquor has been treated for the recovery of soda.

A great deal of investigation has been made on the constituents of waste liquor from the sulphite process of pulp manufacture. Klason<sup>57</sup> has studied particularly the ligninsulphonic acids. Naphthylamine hydrochloride precipitates from the sulphite liquor substances known as  $\alpha$ -ligninsulphonic acids which melt at high temperatures to form a pitch. In cold water this pitch hardens to a friable resin. If a solution of a salt of  $\alpha$ -ligninsulphonic acid is treated with the hydrochlorides of hydroxylamine and  $\beta$ -naphthylamine a white precipitate is formed which when heated slightly yields a yellow resin.<sup>58</sup> A dark brown resin was found by König<sup>59</sup>

as a residue in the distillation of the oily layer from sulphite waste-liquor. Pinabietic acid,  $C_{10}H_{16}O_4$ , which resinifies readily, has been isolated from sulphite liquor by Aschan and Ekholm.<sup>60</sup> (Cf. abietic acid, Chapter 37.)

A plastic resin was produced by Wallace<sup>61</sup> by condensing sulphite waste-liquor with a phenol and aldehyde using ammonium chloride as a catalyst. The quantity of phenols used is at least 25 per cent, and that of aldehydes at least 5 per cent, of the amount of sulphite liquor. The resin is soluble in alcohol and insoluble in water.

Knight<sup>62</sup> suggests fermenting the liquor and removing the alcohol by distillation. The residue, on treatment with phenol or cresol, using various catalysts (hydrochloric acid, caustic soda or potash, lime, zinc chloride), yields a resinous condensation product which on further heating becomes insoluble. It is recommended for varnishes or as a shellac substitute. An interesting variation in this method is to retain the alcohol generated by fermentation and oxidize it to acetaldehyde by addition of potassium dichromate. The phenol is then added and a double condensation is carried out. In one example, fermented waste-liquor containing 100 g. of solids and 1 g. of alcohol was treated with 101 g. of phenol and 8 g. of potassium dichromate. The dichromate not only oxidized the alcohol, but the chromium salt derived in the reaction served as the condensing agent.

A method used by Schmidt<sup>63</sup> to make a resin from sulphite liquor consists in evaporating it to 25 per cent of its volume and treating the concentrate with chlorine for 2 hours. The precipitate is separated and oxidized with a chlorate and hydrochloric acid until the reaction product contains 20 per cent chlorine. The resulting material is stable and can be used as a tanning agent or as a substitute for natural resins. The process was modified by Stinnes<sup>64</sup> who used nitric acid or hydrogen peroxide as an oxidizing agent instead of the chlorate and hydrochloric acid.

Treatment of sulphite waste-liquor with a solution of water glass yields a gelatinous precipitate.<sup>65</sup> When this is dried a resinous substance is obtained which may be mixed with fillers for various purposes. For instance, by mixing it with blast-furnace slag a road-making or building material can be formed.

Several other methods have been suggested for the recovery of resins from sulphite liquor.<sup>66</sup> If the latter is treated with hydrogen sulphide and then with air and a small amount of nitric acid the resins collect in a scum on the surface. Separation of resins is also effected by the addition of crude salt to the liquor. A road-building material can be made by neutralizing sulphite liquor with sodium carbonate or calcium hydroxide, evaporating the solution until it contains 10 per cent moisture and then adding 2-10 per cent of gas tar or pitch. Saponified resins formed by the action of sodium carbonate on sulphite liquor are purified by electrolytic hydrogenation in a 2-compartment cell, the resins being placed in the negative compartment and a 13 per cent sodium carbonate solution in the positive.

The liquid resin obtained in digesting wood to wood pulp is known as tall oil (or tallöl). Fahrion<sup>67</sup> described it as a dark brown, fairly thin oil, soluble in

alcohol, ether and acetone. He found that on distillation tall oil gives products similar to those from common rosin.<sup>66</sup> From the results of several investigators<sup>67</sup> the following principal constituents of tall oil are indicated:

Resin acids.....	30-45 per cent
Fatty acids.....	45-60 " "
Unsaponifiable matter....	6-12 " "

The unsaponifiable portion is a yellow viscous oil containing waxy or pitchy material.

Crude tall oil was described by Hübscher<sup>70</sup> as a dark brown, viscous liquid containing a crystalline sediment of abietic acid (4 per cent). From this crude oil a yellow distillate containing 18 per cent unsaponifiable matter was obtained.<sup>71</sup> The calcium soap of tall oil was found to be a viscous, sticky mass insoluble in alcohol, but soluble in benzene. Its use in plasters and flypaper was suggested. Hübscher isolated tall oil pitch as a glassy, brittle mass (melting at 85°C.), soluble in benzene. He suggested it be used for insulation and as an ingredient in cheap grades of black varnish. Wolff<sup>72</sup> found that drying agents harden tall oil so that it forms a brittle film and can be employed as a constituent of paint.

A refined tall oil was produced by Patch and Dambacher<sup>73</sup> by the oxidation of the crude material. Polymerization and condensation also took place during the reaction, which could be carried out either by bubbling oxygen through the oil or by use of compounds which liberated oxygen in the nascent state (e.g., sodium perborate or sodium persulphate). Temperatures of 85-195°C. for 20-50 hours were employed and in some cases iron, aluminum or manganese resinate served as a catalyst. A clear, odorless, dark oil was obtained. This is recommended as a cutting oil or for coating metals, due to its corrosion-retarding properties.

By the fractional vacuum distillation of tall oil, de Keghel<sup>74</sup> effected a separation into fatty acids, resin acids, rosin oil, unsaponifiable matter and pitch. The distilled fatty acids (tallölein) boiling at about 240°C. were suggested for the making of soft soaps, liquid soaps and toilet preparations, and as a base for various greases and oils. The resin fraction (boiling at 290-320°) was described as a brown, resinous, sticky, saponifiable liquid useful in dark-colored printing inks and in axle greases.<sup>75</sup> It was stated that sulphonation of the resin acids yielded a product which can replace Turkey red oil for some purposes.

Another method is that used by Roll<sup>76</sup> in which selective saponification is effected in an organic solvent. The resin soaps form first and can be withdrawn readily from the fatty acid soaps.

Schultze<sup>77</sup> removed the fatty acids from resin acids by an esterification process.

<sup>66</sup> The use of this resin as a substitute for colophony was suggested by P. Klemm (*Chem.-Ztg.*, 1910, 34, 1353; *J.S.C.I.*, 1911, 30, 37).

A mixture of tall oil (100 parts), alcohol (25 parts) and concentrated sulphuric acid (4 parts, specific gravity 1.84) is heated under reflux for two hours, causing esterification of fatty acids but leaving the resin acids unaffected. Sulphuric acid is removed and the ester mixture is treated with caustic soda solution in slight excess of that needed to neutralize the resin acids and the residual sulphuric acid. The mixture is then stirred with benzene, resulting in the formation of two layers, the upper one containing fatty acid esters dissolved in benzene, and the lower one the sodium soaps of resin acids in water-alcohol solution. The layers are separated and the fatty acids and resin acids recovered.

In the method of Franzen and Held<sup>78</sup> the resin and fatty acids were esterified simultaneously with a polyhydric alcohol (e.g., glycerol or ethylene glycol). The resulting mixture was heated with water in the presence of a catalyst, thus hydrolyzing the fatty esters but not the resin acid esters. Free fatty acids were then separated from resin acid esters by steam distillation. In one instance refined tall oil was treated with excess glycerol and a small amount of tin powder. Esterification was complete after 4 hours heating at 230°C. The fatty acids were liberated by heating the mixed esters with water at 180°C. in an autoclave with zinc dust as a catalyst. Still another procedure consists in treating a warmed solution of tall oil in mineral oil with sufficient sulphuric acid to effect separation of resins.<sup>79</sup> Levi<sup>80</sup> removed pitchy material from tall oil by precipitation with petroleum benzene.

By mixing tall oil (2 parts) with glue or gelatin (1 part) and water (1 part) an emulsifying agent for oils or bituminous substances is formed.<sup>81</sup> A core-binding composition for castings is made from the oil blended with a drying oil (linseed oil), a solvent (pine oil) and either dextrin, molasses, glue or starch.<sup>82</sup> The ingredients may be emulsified with an alkali or with cobalt linoleate. Addition of cresols, hydrocarbon oils, or wood tar to tall oil yields a preservative coating for wood.<sup>83</sup> An adhesive for catching insects consists of chlorinated tall oil incorporated with such substances as carnauba wax, castor oil, bleached wax acids and esterified ozokerite.<sup>84</sup>

An emulsifying agent is obtained when tall oil is esterified with an aliphatic polyhydric alcohol (glycerol), using calcium or magnesium glycerate as a catalyst, and the ester is sulphonated with sulphuric acid, oleum or sulphuric acid monohydrate at temperatures below 40°C.<sup>85</sup> Also, sulphonation of other esters or amides<sup>86</sup> derived from this oil, or of a mixture of the oil (100 parts) and phenol (30 parts) gives water-soluble products which may be utilized in the textile industry,<sup>87</sup> for example, as dispersing agents. Partial reduction of tall oil constituents gives aliphatic ketones which may be sulphonated to yield wetting or dispersing agents.<sup>88</sup> Textile oils<sup>89</sup> or cleansing agents are made also by emulsifying tall oil with a fatty acid soap and aniline,<sup>90</sup> or by mixing the oil with vegetable

oils and heating the mixture *in vacuo*, treating with superheated steam, and then allowing the liquid to cool in an inert atmosphere.<sup>91</sup>

Grohn<sup>92</sup> prepared coating compositions by dissolving in benzene (or a similar solvent) the esters derived from tall oil and polyhydric alcohols or phenols. Drying oils, pigments and driers can be added if necessary. A sizing composition for paper consists of ordinary rosin size incorporated with not more than 30 per cent of refined tall oil resin. This procedure lowers the melting point of the composition.<sup>93</sup>

Plastic masses for electrical or heat-insulation are made by mixing the distillation residues of tall oil, or of natural resins, with sulphur, heating the mixture until it becomes ropy, and then incorporating it with fillers (e.g., asbestos) and the condensation products of acetylene or of aldehydes, e.g., phenol-formaldehyde.<sup>94</sup>

### RESINS FROM CARBOHYDRATES

Although many of the products mentioned in this section can be considered modifications of synthetic resins discussed elsewhere in the text (e.g., phenol-aldehyde and urea-aldehyde resins), they are grouped together because of the convenience of classification. Since in this work classification is primarily one of starting materials, those resins derived from carbohydrates, viz., plant materials, are assembled here. Carbohydrates are aldehyde-alcohols, ketone-alcohols or compounds which are converted by hydrolysis into aldehyde-alcohols or ketone-alcohols. Formaldehyde has been polymerized to carbohydrates by the action of bases.<sup>95</sup> Carbohydrates would be expected, therefore, to be convenient and cheap sources for the production of synthetic resins by reaction with urea or phenol.<sup>96</sup>

Resins said to be suited for molding or forming into sheets and films were made by Ford<sup>97</sup> by the condensation of saccharides with aldehydes and urea.<sup>98</sup> When sucrose was used as the saccharide the product was colorless and transparent. The employment of molasses and cane sugar resulted in dark resins. As an example cane sugar (300 parts) is dissolved in 36 per cent formalin solution (250 parts) and the mixture is heated gently (100-105°C.) until all reaction ceases. Then the liquid is heated to boiling and a small amount of hexamethylenetetramine (10 parts) is added. Boiling is continued and urea (75 parts) is introduced in small quantities at a time. When all the urea has reacted, the viscous material is immediately poured into molds and allowed to harden in the air.

A resin with different characteristics is obtained if phthalic anhydride is used instead of urea.<sup>99</sup> Reaction is carried out as described above until after the hexamethylenetetramine has been added. The mixture is heated to 180°C. and then phthalic anhydride (300 parts) is added in small portions. When reaction is complete the mass is cooled to 90°C. and maintained there for several hours to remove water. The liquid is poured into molds to cool, yielding a water-white, non-resilient substance. It is somewhat brittle, giving a sharp fracture, and is soluble in ace-

tone and similar solvents. If moisture is removed by heating at temperatures higher than 90°C. the products will range in color from light yellow to jet black, depending on conditions. The black color is obtained by heating at 250°C. for 10 hours. The phthalic anhydride resin can be pulverized and mixed with inert bodies (e.g., powdered glass wool), synthetic or natural resins, cellulose derivatives, drying oils or reclaimed rubber or it may be dissolved in ether, acetone, amyl acetate or toluene for use as a varnish.

The employment of phthalic acid in place of the anhydride as well as the use of tartaric, malic and similar aliphatic acids yielded clear, water-white bodies with the same general characteristics.<sup>100</sup>

A variation of this method<sup>101</sup> involves reacting urea directly with a carbohydrate (e.g., cornstarch), using 50 per cent sulphuric acid to assist condensation. A methylene hardening agent is then added and the final product obtained by heating.

Hawerlander<sup>102</sup> has hardened sugar-formaldehyde resins either by heating or by exposure to the atmosphere. For instance, brown cane sugar is dissolved in twice its weight of 40 per cent formaldehyde and the solution is heated at 40°C. for 10 minutes. The resulting liquid is then ready to be used as a binder in making molded articles from fibrous material. The solution will set within 24-48 hours in the air or in 6-10 minutes at 200°C., yielding a hard, plastic material. Setting may be accelerated by adding about 2 per cent (of the weight of sugar) of sodium sulphite to the reaction mixture. Plastic masses are formed also by the condensation of formaldehyde with starch, using as accelerators various organic acids together with a small amount of an inorganic acid<sup>103</sup> (e.g., sulphuric acid with lactic acid or phthalic anhydride).

A textile finish<sup>104</sup> is obtained from starch by condensing it with an aldehyde or with hexamethylenetetramine while cold. When used to treat fabrics and dried in a slightly acidic condition, resistance to washing is secured.

Meigs<sup>105</sup> has described the condensation of carbohydrates with phenols, amines and organic acids. The products are black in color, water-insoluble and said to be useful in baking-type lacquers and molding compositions. The following is an example of the reaction between carbohydrates and organic acids: Glucose (126 parts), dextrin (54 parts), salicylic acid (138 parts), aniline (20 parts) and water (100 parts) are mixed together and refluxed for 45 minutes, yielding a black, resilient mass. For treatment with amines one procedure is to reflux for 2 hours a mixture of glucose (360 parts), aniline (150 parts), water (125 parts) and oxalic acid (5 parts), forming a semi-solid material which becomes infusible when heated above 125°C.

To effect combination of carbohydrates and phenols, a mixture, for example, of glucose (360 parts), phenol (170 parts), water (200 parts), aniline (30 parts) and oxalic acid (4 parts) is heated under reflux for 3.5 hours yielding a black resin (360 parts) which can be hardened by the addition of 5 per cent of hexamethylenetetramine and heating to 160°C.

Sucrose<sup>106</sup> also condenses with phenol, with either mineral or organic acids as cata-

<sup>106</sup> J. V. Meigs, U. S. P. 1,845,314, Feb. 16, 1932, to Meigsoid Corp. This application and the application for U. S. P. 1,832,038, Nov. 17, 1931, were involved in interference with applications of McIntosh corresponding to U. S. P. 1,753,030, April 1, 1930, and 1,820,816, Aug. 25, 1931, to Continental Diamond Fibre Co.

lysts, to form a black, almost tarry mass which can be hardened by heat or exposure to air, as well as by use of a variety of condensing agents including acids, bases, salts and benzyl chloride.<sup>107</sup> Phenol (600 parts) and 500 parts of a sugar containing 84 per cent dextrose are heated with 5 parts of sulphuric acid, the water being removed through a fractionating column as fast as it is formed.<sup>108</sup> Excess phenol is removed by vacuum distillation. The black resin secured by the apparent interaction of 1 mol of dextrose and 2 mols of phenol melts to a viscous liquid which may be hardened by heating to 140°C. with 3-10 per cent of hexamethylenetetramine. Other materials (e.g., furfural and aniline, the naphthols, glycerol and naphthylamines) may be used instead of phenol. It has been stated that greater proportions of hexamethylenetetramine (10-20 per cent of the weight of phenol-carbohydrate) tend to increase the mechanical strength of molded objects made from these resins.

It was reported by Meigs<sup>109</sup> that the properties of phenol-carbohydrate resins are modified by certain fillers usually employed in molding compositions. The more difficultly water-soluble metallic bases in particular are said to improve electrical properties of molded articles. It is considered that these bases react with other constituents of the resin, probably with decomposition of water-soluble substances. Insulation resistance is reported to be increased ten-fold by the incorporation of about 10 per cent of calcium hydroxide.<sup>110</sup> The usual procedure is to add the metallic compound to the fusible carbohydrate-phenol resin, together with a hardening agent, followed by hot-molding at 150-180°C. Another method<sup>111</sup> involves the use of fatty oils, or pitches from the distillation of these oils. For example, 960 g. phenol, 400 g. corn sugar (85 per cent dextrose), 240 g. tung oil and 13.6 g. concentrated sulphuric acid were heated at 180-190°C. until most of the water was removed. Apparently the oil took part in the condensation, since the reaction product, a reddish-brown mass, dissolved completely in alcohol, which is not a solvent for tung oil.

A dark, viscous body was obtained by McIntosh<sup>112</sup> by heating equal parts of starch, phenol and water, with sulphuric acid as a catalyst, for several hours under reflux. This material was soluble in acetone, alcohol and benzene and consequently was suggested as a varnish base. Hardening was attained by heating at 125°C. for 10-12 hours, the reaction being accelerated by pressure and by addition of hexamethylenetetramine, benzidine-acetone or sodium-acetone-bisulphite. The ultimate product was hard, infusible and insoluble in most solvents. By impregnating fibrous or porous material with a resin of intermediate stage and molding in laminated form, a composition useful in making gears, insulators and sound-records was secured. The final resin was improved by removing or neutralizing the catalyst after the initial condensation. Modifications in the method include substitution of sugars or of other carbohydrates for starch as well as the use of other phenols and the employment of pyridine, aniline hydrochloride or sulphur monochloride as catalysts.

The use of catalysts, especially mineral acids, in condensations of carbohydrates and phenols has the disadvantage of introducing in the resin substances which increase moisture-absorption, decrease electrical strength and corrode metal dies during molding. Moreover, these undesirable features are difficult to eliminate. By carrying out the reaction between starches or sugars and phenols in a closed vessel

<sup>112</sup> J. McIntosh, U. S. P. 1,753,030, April 1, 1930, and 1,820,816, Aug. 25, 1931, to Continental Diamond Fibre Co.; *Chem. Abs.*, 1930, 24, 2624; 1931, 25, 5790. British P. 231,553, 1923; *Chem. Abs.*, 1925, 19, 903.

at 200-260°C., Novotny and Romieux<sup>113</sup> succeeded in condensing these materials without a catalyst. The pressure generated during the reaction, as well as the high temperature, facilitated the process. A brownish-black, hard lustrous resin was obtained by heating 100 pounds of corn starch and 150 pounds of phenol in a pressure kettle at 250°C. for 2-3 hours and then removing uncombined phenol by distillation. The product may be more fully cured by additional heating and by use of the usual aldehyde type of accelerators. Urea has been suggested as a substitute for phenol.<sup>114</sup>

Konther<sup>115</sup> suggests that phenol-carbohydrate resins, after washing with water, be dissolved in methyl or ethyl alcohol to give a black enamel varnish which is resistant to heat. As a modification, 20 parts of rubber are dissolved in the resin by the application of heat and pressure.<sup>116</sup>

Phenol, formaldehyde and a carbohydrate were condensed with an alkaline catalyst by Loetscher<sup>117</sup> to a sufficient degree only to form a water-soluble resin, which could be used in aqueous solution for laminated or veneered articles, or dried and admixed with wood flour for molding purposes. One such product is secured by heating phenol, 40 per cent formaldehyde and a 50 per cent cane sugar syrup in equal parts at 93-108°C. with about 2 per cent of dilute sodium or potassium hydroxide solution. The reaction is stopped just before the resin reaches its water-insoluble state. When starch is substituted for cane sugar, much larger quantities of water and caustic alkali are required.

The resistance of fusible phenol-carbohydrate resins to ammonia and to water was improved by Meigs<sup>118</sup> by a heat-treatment at 240-270°C. for 2-3 hours in a high-boiling solvent (b.p. 270-300°C.). The resultant compound is firm and hard, yet fusible enough for molding or milling on hot rolls and soluble in alcohol, acetone and benzene. In one instance, 800 g. of the intermediate substance were heated with 190 g. of creosote oil residue (b.p. over 300°C.). The resin obtained was mixed with wood flour and hexamethylenetetramine and cured in a mold at 120°C., to yield a glossy, moisture-resistant material.

An alcohol-soluble body was produced by Bau<sup>119</sup> by condensing formaldehyde, a phenol and an aldose (e.g., glucose) in the presence of hydrochloric acid at 65-70°C. According to Bau, the hydroxybenzyl alcohol resulting from the interaction of phenol and formaldehyde forms a glucoside, and subsequent polymerization takes place.

Hard infusible products were made by Tarassov<sup>120</sup> by the condensation of wheat starch, potato flour or potato molasses with formaldehyde, a phenol and a sulphonated hydrocarbon (e.g., naphtha sulphonic acids).

Meigs also obtained resins from carbohydrates and polyhydric alcohols.<sup>120</sup> In this procedure a small amount of a mineral acid is used and presumably decomposes the carbohydrate into humic acid derivatives which then combine with the alcohol to form a resin. Reaction takes place in a vessel equipped with a reflux condenser maintained at such a temperature that water vapor will escape but alcohol vapors will be condensed to return to the reaction vessel. To 400 parts of glycerol at 100°C. are added 6 parts of sulphuric acid (sp.gr. 1.84), followed by 400 parts of corn sugar (crude

dextrose) and the mixture is heated for 4 hours at 190-230°C. The reaction product is washed with hot water and then dried at 100°C. yielding a dark brown, glossy, thermoplastic mass, which can be mixed with fillers for the preparation of molded articles. The resin is made infusible by heating it for about 1 hour at 130-160°C. A modification of this method<sup>121</sup> is to digest a carbohydrate, e.g., dextrose, molasses, starch or levulose, with caustic soda to form sodium salts of organic hydroxy acids, after which butyl alcohol, glycerol, diethylene glycol or other alcohols are added, together with hydrochloric acid. The latter liberates the organic acids from their salts and acts as a catalyst to bring about a reaction between these acids and the alcohol. Resinous substances are formed, compatible with cellulose compounds and soluble in ethyl and butyl acetate or other esters and in alcohols. The product may be purified by washing with water to remove salts, or by extraction with alcohol.

Light-colored, resinous bodies are said to be formed by the condensation of cyclic ketones with carbohydrates and with polyhydric alcohols (other than a polyvinyl alcohol) containing at least 6 carbon atoms.<sup>122</sup> (With some of the reagents the products are crystalline.) In one case, 100 parts of sucrose are suspended in 100 parts of methyl alcohol to which 0.25-0.5 per cent of concentrated sulphuric acid has been added. The sugar is dissolved by heating under reflux on a water bath. The solution is cooled and 300-400 parts of 2-methylcyclohexanone and 40 parts of concentrated sulphuric acid are added. This mixture is agitated at 0-5°C. for 4 hours and then neutralized with sodium carbonate. After the removal of excess methylcyclohexanone there is obtained a solid, transparent resin which is soluble in many organic solvents but only slightly in benzene.

Weiss<sup>122a</sup> produced a water-soluble resin by reacting dextrose with acid anhydrides. Thus 50 parts of maleic anhydride and 75 parts of phthalic anhydride are heated with 180 parts of dextrose at 150°C. Further heating tends to reduce the solubility.

Sucrose and other carbohydrates when heated with persulphates yield hard, insoluble and infusible oxidation products according to Böhrer.<sup>123</sup> E.g., 50 parts of crude sugar are dissolved in 50 parts of alcohol (50 per cent) and treated with 3 parts of ammonium persulphate. The solution is evaporated and the residue heated to 180°C. yielding a water-insoluble mass. The hardness and elasticity of the resin are modified by the addition of oils or other resins to the above solution before evaporation. The material can be mixed with fillers to make molded products.

The action of phloroglucinol on sugars without the application of heat was studied by Fischer and Jennings<sup>124</sup> but they did not succeed in isolating any stable substances. Counciler<sup>125</sup> obtained condensation products of phloroglucinol with various aldehydes and sugars (e.g., with acetaldehyde, dextrose, mannose, galactose, levulose and arabinose). A solution of 6 g. of dextrose and 5.4 g. of phloroglucinol in 30 cc. of water, on treatment with hydrogen chloride gas, slowly thickened and turned reddish-brown. The product, when purified, was an amorphous yellow-green to olive-green precipitate. It was almost insoluble in water, ether and benzene, but dissolved in alcohol. Heated to 200°C. it carbonized but was non-combustible. The analysis gave its empirical formula as  $C_{12}H_{10}O_8$ , which represents the condensation of 1 mol of dextrose and 1 mol of phloroglucinol with the elimination of 3 mols of water. Other results are shown in Table 36.

Resinous substances were also obtained by Counciler<sup>126</sup> from phloroglucinol and formaldehyde, acetaldehyde, propionaldehyde and isobutyraldehyde.

Various processes for the utilization of hulls and spent glutes have been devised. Gluten and waste from starch works, for instance, can be kneaded with phenolic materials which form an insoluble compound with the vegetable proteins, according to Basset.<sup>127</sup> The paste of gluten and phenol may be used for the manufacture of plastic substances or treated with acetone or a similar solvent to separate the gluten from the phenol. Preparation of resins from spent grains or malt is also described by Basset.<sup>128</sup> These materials are condensed with phenolic bodies using sodium hydroxide, zinc chloride or sodium zincate as a catalyst. Formaldehyde may also be used in the operation. The resulting resin has been suggested for thermal and electrical insulation. Resinous material soluble in organic solvents was prepared by Tzonev and Yavnel<sup>129</sup> by heating the hulls of sunflower seeds at over 100°C. with phenol and a mineral acid catalyst. The reaction was assumed to be a condensation of phenol with furfural, glucose, xylose and other products of hydrolysis.

A distinction is made by Maksarov and Andrianov<sup>130</sup> between resinous starch esters, which they term semi-synthetic resins, made from pure starch, and the benzylated derivatives of starchy substances such as potatoes, flour and bran. The latter contain proteins, amino acids and other analogous compounds in addition to carbohydrates and form condensation products, which are considered to be true resins and are classifiable as "benzylamylonic esters."

Molasses and molasses residues are suggested as a source of non-sugar organic matter capable of conversion into hard, heat-resistant resins for making bricks and tiles. According to Vazquez<sup>131</sup> the molasses is extracted with a mixture of sulphuric acid, alcohol and organic solvents (e.g., chlorinated hydrocarbons) which do not dissolve sugar. After stirring at 25-30°C. until the mass is uniform, a dark liquor is allowed to separate. This contains the solvents and organic salts and other impurities from the molasses. On evaporation, a residue is left which solidifies on cooling and hardens at 100°C. or higher to an insoluble, infusible resin, which may be ground and used with a binder for molding. If the liquor from the extraction operation is concentrated to a thick syrup it can serve as a binding agent for the hardened product. The mixture is adaptable for cold molding followed by baking at gradually rising temperatures to 250°C.

Methods for the preparation of resinous condensation products of pectous matter obtained from plants have been devised by Hawerlander.<sup>132</sup> The non-fibrous constituents of cereal straws, plant stalks and grasses are obtained by agitating the plant material with water or steam. The aqueous solution of non-fibrous substances is removed by pressing the fibers and is then evaporated, yielding the pectous residue as a dark brown, viscous mass. This is mixed with an equal volume of 40 per cent formaldehyde and the mixture thoroughly agitated. The temperature is raised to 30°C. and small quantities of sodium sulphite (or other

<sup>132</sup> A. Hawerlander, U. S. P. 1,941,349 and 1,941,350, Dec. 26, 1933, to Albert D. Stewart; *Chem. Abs.*, 1934, 28, 1484, 1536.

condensing agent) are added from time to time until the amount used equals about 1 per cent of the volume of reactants. External heating is not necessary because of the exothermic nature of the reaction. When the mixture has attained a temperature of 70°C. it is cooled to about 25°C. The product is fusible and water-soluble but becomes insoluble on exposure to air. The material can be mixed with fillers and fibers and molded; heat and pressure rendering it infusible.

Hawerlander produced a resin possessing many of the characteristics of phenol-formaldehyde compounds by condensing pectose with an aldehyde and a ketone.<sup>122</sup> This resin, which he terms a pectose resin, is clear and amber-like, melting at 70°C.

As an example of the preparation of such a resin, equal parts of pectous residue (mentioned above), formaldehyde (36-40 per cent) and dimethyl ketone are mixed together and stirred for 6 hours at 35°C. Caustic potash is added during this treatment. When the liquid is subsequently allowed to settle three layers form, the top containing the fat and wax constituents, the bottom a residue and the middle (85 per cent of the total) the desired reaction mixture. The middle layer is removed and treated further with caustic potash, yielding a gummy liquid which solidifies when neutralized with dilute nitric acid. Evaporation of volatile liquids yields a residue of clear amber-like resin. This can be used in lacquers and in molded materials. It is made infusible and insoluble by heating with a hardening agent (e.g., hexamethylenetetramine).

The possibility of the commercial production of xylose from cottonseed hulls<sup>124</sup> led to investigations on the formation of varnish resins from this sugar.<sup>125</sup> Equimolecular proportions of xylose and aniline (150 parts and 92 parts, respectively) when heated at 75-80°C. for 10 minutes yield a clear red resin soluble in acetone. The solution is said to give on wood a varnish resistant to hot water, alkalies and acids (except nitric).<sup>126</sup> The varnish can be made more cheaply by using impure cake-xylose and aniline oil.<sup>127</sup>

It was observed that methylated xylan (by action of methyl sulphate in alkaline solution) tends to form gummy products.<sup>128</sup> The mono-allyl ethers of corn and potato starches and of dextrin and inulin have been described as gummy substances.<sup>129</sup> Sucrose octa-acetate (obtained from sucrose, sodium acetate and acetic anhydride) possesses a crystalline form, but when fused (melting point 69°C.) and cooled it changes to a clear, transparent glass suggesting its use in resins and plastics.<sup>130</sup> Condensation of dulcitol,  $C_6H_{12}O_6$ , with o-nitrobenzaldehyde yields 1,2,5,6-bis(o-nitrobenzylidene)dulcitol, which when isomerized by the action of light, produces a resin.<sup>131</sup>

Hashitani<sup>132</sup> reports that some derivatives of yeast-gum are amorphous or resinous in character. Thus, benzoyl yeast-gum,  $C_6H_5O_5(C_6H_5CO)_3$ , is a whitish, amorphous material, soluble in pyridine and melting at 223-225°C. Depolymerization of yeast-gum with glycerol at 210-220°C. for 4-5 hours gave a substance,  $\alpha$ -yeast-gum, which was white, amorphous, hygroscopic and soluble in water.

## Chapter 37

### Hardened Rosin. Resinates

Among the natural resins the most important is common rosin or colophony obtained from various species of pine trees. Until the advent of tung oil varnishes,<sup>1</sup> rosin was much despised as a natural resin because of the harmful effect produced by its acidic constituents. The present discussion deals with the disadvantages of rosin in its natural state and presents many of the attempts made to convert the resin into a more useful material. The melting point of rosin averages about 80°C., the acid number about 160 and the saponification number about 165.<sup>2</sup>

The amount of gum rosin produced yearly in the United States is at least 300,000-325,000 tons and of wood rosin is about 100,000 tons.<sup>3</sup> Gum rosin is obtained as the residue in the separation of spirit of turpentine from crude turpentine pitch by distillation and wood rosin is procured by naphtha extraction of waste pine-wood after it has been steam distilled to recover pine oil and turpentine.<sup>4</sup> The principal uses for rosin are in the paper, soap<sup>5</sup> and paint and varnish industries.<sup>6</sup> Of growing importance are its uses in modified synthetic resins, adhesives, emulsifiers, waterproofing material and dehairing preparations. Although rosin is a natural resin it is rarely used directly (because of its acid nature) but is converted into soaps or esters.<sup>8</sup> The fact that it is usually made into a modified product justifies the consideration of rosin in a work on synthetic resins.

#### ABIETIC ACID

The principal constituents of American rosin are abietic acid (more than 90 per cent) and a small amount of non-acid material called resene.<sup>9</sup> Considerable work has been done on the determination of the structure of abietic acid. Ruzicka and his co-workers<sup>10</sup> give as the structure the following:

<sup>1</sup> See Chapters 28-29.

<sup>2</sup> The physical properties of wood rosin have been studied by J. M. Peterson, *Ind. Eng. Chem.*, 1932, 24, 168. A comparison of French and American gum rosins was made by A. R. Hitch, *Ind. Eng. Chem.*, 1931, 23, 1185. For a discussion of wood rosin and gum rosin see A. Zinoviev, *Masloboino Zhirovoe Delo*, 1928 (10), 24; *Chem. Zentr.*, 1929, 1, 3040. A study of the viscosity-temperature relationship of molten rosin is given by J. M. Peterson and E. Fragoff, Jr., *Ind. Eng. Chem.*, 1932, 24, 173. See also H. E. Nash, *ibid.*, 177.

<sup>3</sup> O. Wilson, *Ind. Eng. Chem. News Ed.*, 1934, 12, 170. The estimated world production of rosin is 600,000 tons. The paper industry absorbs 38 per cent, the soap trade 24 per cent and the varnish industries 21 per cent of this amount. See A. J. Gibson, *J.S.C.I.*, 1934, 53, 989.

<sup>4</sup> See R. C. Palmer, *Ind. Eng. Chem.*, 1934, 26, 703.

<sup>5</sup> See A. Campbell, *Ind. Eng. Chem.*, 1934, 26, 718.

<sup>6</sup> J. McE. Sanderson, *Ind. Eng. Chem.*, 1934, 26, 711. See also F. W. Hopkins, *Am. Paint J.*, 1930, 14 (38), 68; *Chem. Abs.*, 1930, 24, 4409.

<sup>7</sup> O. A. Pickett and J. M. Schantz, *Ind. Eng. Chem.*, 1934, 26, 707.

<sup>8</sup> Rosin esters are considered in Chapter 38.

<sup>9</sup> For some of the analyses of rosin see E. Stock, *Farben-Ztg.*, 1921, 27, 156, *et seq.*; *Chem. Abs.*, 1922, 16, 504. L. P. Zhereboff, *Bumazhnaia Prom. (Russia)*, 1923, 2 (1), 59; *Chem. Abs.*, 1924, 18, 1197. E. Knecht and N. B. Maurice, *J. Soc. Dyers Colourists*, 1925, 41, 356; *Chem. Abs.*, 1926, 20, 299. D. N. Shaw and L. B. Sebrell, *Ind. Eng. Chem.*, 1926, 18, 612. A study of color tests for abietic acid was made by W. A. LaLande, Jr., *J.A.C.S.*, 1933, 55, 1536.

<sup>10</sup> L. Ruzicka, P. J. Ankersmit and B. Frank, *Helv. Chim. Acta*, 1932, 15, 1289; *Brit. Chem. Abs. A.*, 1932, 1254. L. Ruzicka, H. Waldmann, P. J. Meier and H. Hösli, *Helv. Chim. Acta*, 1933, 16, 169; *Chem. Abs.*, 1933, 27, 2154. See also R. D. Haworth, *J.C.S.*, 1932, 2717.

Much of the new light on this structure was given by studies in the diene synthesis. (See Chapter 40.) The reaction of methyl abietate and maleic anhydride at  $160^{\circ}\text{C}$ . yields an additive compound of the formula  $\text{C}_{26}\text{H}_{34}\text{O}_5$  which on hydrolysis passes over into the anhydride-carboxylic acid  $\text{C}_{24}\text{H}_{32}\text{O}_5$ . This same compound is obtained from American colophony by direct treatment with maleic anhydride. The fact that maleic anhydride does react indicates that a diene system exists in part.<sup>11</sup> There is only a partial reaction of ethyl abietate with maleic anhydride, showing that the natural acid is a mixture of isomerides.

All investigators do not agree with the above formula. There is still some disagreement on the position of the carboxyl group<sup>12</sup> though the principal controversy is on the position of the two double bonds. Vocke<sup>13</sup> placed them in the 7, 8 and 9, 14 positions whereas Arbuzov<sup>14</sup> suggested either the 7, 8 and 13, 14 or the 6, 7 and 5, 13 positions.<sup>15</sup>

Many methods have been devised for obtaining pure abietic acid from rosin.<sup>16</sup> (Crystals of abietic acid are shown in Figure 119.) The presence of resene exerts some influence on the reactivity of abietic acid, interfering with esterification and promoting oxidation.<sup>17</sup> One of the earliest ways of procuring pure abietic acid was to digest rosin with 70-90 per cent alcohol, precipitate with hydrochloric

<sup>11</sup> See B. Arbuzov, *Gen. Chem. (U. S. S. R.)*, 1932, 2, 806; *Chem. Abs.*, 1933, 27, 2688; *Brit. Chem. Abs. A*, 1933, 392.

<sup>12</sup> For instance, M. Farnica (*Bull. inst. pin.*, 1933, 151, 181; *Chem. Abs.*, 1934, 28, 160) places the carboxyl group in position 4.

acid, and recrystallize in methyl alcohol.<sup>22</sup> In the method of Steele<sup>23</sup> rosin is boiled under reflux for 2 hours in 98 per cent acetic acid. The mixture is then filtered and the filtrate allowed to crystallize.

In the opinion of Dupont and co-workers<sup>24</sup> abietic acid is not present as such in rosin, but is formed by isomerization at high temperatures<sup>25</sup> or under the influence of strong acids. Isomerization is obtained by passing a slow stream of hydrogen chloride through fused rosin at 150°C. for 15 minutes or by boiling an alcoholic rosin solution with concentrated hydrochloric acid. Abietic acid is purified by suspending rosin in alcohol and adding enough alkali to neutralize one-fourth of the acid.<sup>26</sup> An acid salt,  $C_{30}H_{48}O_8Na \cdot 3C_{30}H_{48}O_8$ , crystallizes out<sup>27</sup> which may be separated and further saponified to yield pure rosin soaps or may be decomposed by strong acids to regenerate pure abietic acid.<sup>28</sup>

FIG. 119.

Typical Cluster of Abietic Acid Crystals. (O. A. Pickett and J. M. Schantz.)

Courtesy Industrial and Engineering Chemistry

Kressman<sup>29</sup> employed a distillation method for the separation of abietic acid and resene. The distillation is carried out at less than 10 mm. pressure in order to avoid decomposition. Under these conditions resene distills principally at 205-240°C. and abietic acid at 240-260°C. A somewhat similar method was used by Gammay.<sup>30</sup> He assumed that no resene is present in crude turpentine gum but that it is formed in the usual distillation method for obtaining rosin and spirit of turpentine. By distilling crude gum *in vacuo* below 110°C. with a small amount of saturated steam, Gammay obtained in 72 per cent yield a rosin with 0.8 per cent resene.

The vacuum-distillation (2 mm. press.) of wood rosin yields a fraction containing 93 per cent abietic acid which can be purified by dissolving in 80 per cent ethyl

alcohol and recrystallizing.<sup>27</sup> The mother-liquor is concentrated and its residues are fractionally distilled for further recovery of abietic acid.

Pure abietic acid can be prepared also by steam-distillation.<sup>28</sup> It is believed that highly superheated steam causes a physical dispersion of the aggregated molecules in rosin so that in steam-distillation very little decomposition occurs. Abietic acid is obtained in 86-96 per cent yield in distillation at 240-250°C.

Gnaedinger<sup>29</sup> obtained  $\alpha$ -abietic acid by heating French rosin with oxalic acid at 140-160°C. The resulting product is purified by crystallization in alcohol. Abietic anhydride (m.p. 149°C.) is obtained by boiling pure abietic acid with acetic acid anhydride.<sup>30</sup> Another method of obtaining abietic anhydride was used by Mossgraber.<sup>31</sup> Rosin is dissolved in ethyl alcohol containing 10 per cent of caustic soda. The solution is treated with acetyl chloride, and upon heating, ethyl acetate distills off leaving a residue of sodium chloride and abietic anhydride. The use of the latter in insulating-varnishes was suggested.

#### PURIFICATION OF ROSIN

Low-grade rosins are objectionable in the making of soaps because of the discoloration imparted by impurities. Consequently a number of methods have been devised for purifying rosin.<sup>32</sup> In one method, after the usual distillation of crude turpentine the distillation is continued under very high vacuum to produce a pure colophony.<sup>33</sup> For the purification of wood rosin it is distilled repeatedly at 270-330°C. under such sufficiently reduced pressure that very little decomposition occurs.<sup>34</sup> A continuous process for low-pressure distillation of wood rosin was devised by Schultze.<sup>35</sup> The material is heated to 180-255°C. and the resulting liquid is spread in a thin layer 3 to 4 mm. thick on a surface heated to about the same temperature as the liquid introduced. The desired pressure (as low as 1 mm.) is maintained over this surface, the vapors are collected and condensed and the non-volatile portion is removed from the surface continuously. An analogous method was used by Gubelmann and Lee.<sup>36</sup> It is stated that partial decolorization of low-grade rosin is effected by low-pressure distillation (10-20 mm.) at 250-290°C. in the presence of 0.3-1.0 per cent boric acid or borax.<sup>37</sup>

In a distillation method used by Hitch<sup>38</sup> the rosin is dissolved in turpentine or gasoline and the solution is sprayed into a zone heated to about 340°C. and kept under high vacuum so that vaporization is almost instantaneous. The purified rosin is collected by fractional condensation, it condensing at a lower temperature (about 210°C.) than the color-containing impurities (about 270°C.).

It was found by Hall<sup>39</sup> that the dark color of some rosins is caused by the oxidation or decomposition of constituents of acid and carbohydrate nature. Since these constituents are water-soluble in the original oleoresin it was suggested that lighter

<sup>39</sup> J. A. Hall, *Ind. Eng. Chem.*, 1932, 24, 1247.

rosins can be produced by washing the oleoresin with steam before distilling. Factors to control in the process include prevention of exposure of the gum to oxidation and use of apparatus free from iron.

Humphrey<sup>40</sup> treated impure rosin with a low-boiling hydrocarbon (boiling point less than 15°C. e.g., liquid butane) having a selective solvent action for the pure rosin. The solution is separated from the impurities and the rosin (75 per cent yield) is recovered by evaporation of the solvent. In similar methods methyl alcohol or a polyhydric alcohol is used.<sup>41</sup>

A different process consists in dissolving rosin in a solvent such as gasoline and treating with an organic ester (e.g., monacetin) which is immiscible with the rosin solution but dissolves out the coloring matter.<sup>42</sup> Other substances used as selective solvents include alcohols and glycols, phenols and such ethers as guaiacol or ethylene glycol monoethyl ether.<sup>43</sup>

A gasoline solution of rosin is freed of impurities by precipitation with an anhydrous metal chloride (e.g., zinc or stannic chloride).<sup>44</sup> Logan<sup>45</sup> employed essentially the same method using light-colored metal halides to precipitate the impurities from a 10 per cent solution of rosin in naphtha. To remove iron compounds rosin is treated in liquid phase with either oxalic or citric acid and the resulting product is extracted with petroleum naphtha.<sup>46</sup>

In a process of Palmer and Henke<sup>47</sup> rosin is dissolved in petroleum naphtha and resorcinol (90% aq.soln.) is added at 90-110°C. The mixture is stirred and allowed to settle so that the resorcinol layer containing the impurities can be separated. For further purification the rosin is treated with fuller's earth or charcoal.<sup>48</sup>

Resorcinol was used also by Borglin<sup>49</sup> as a solvent for rosin impurities. The rosin is dissolved in gasoline and the resorcinol is dissolved in an aliphatic alcohol (e.g., ethyl alcohol) with which the rosin solvent is immiscible. The two solutions are mixed together to dissolve the impurities and then are easily separated for the recovery of the pure rosin. In another of Borglin's methods the second solution consists of oxalic acid in 92 per cent ethyl alcohol.<sup>50</sup>

Kaiser and Hancock<sup>51</sup> used furfural as a selective solvent for rosin impurities. Low-grade wood rosin is dissolved in gasoline and then furfural is added. On refrigeration a layer settles out containing some rosin and a major portion of the furfural in which the impurities are contained. The remaining solution yields high-grade wood rosin in 70-75 per cent yield. A medium-grade rosin is recovered from the impure layer by gasoline extraction. In a modification of the process the furfural is replaced by either a phenol, a chlorohydrin, furfuryl alcohol,

sulphur dioxide or aniline.<sup>53</sup> Hancock<sup>54</sup> treated rosin (dissolved in gasoline) with furfural or phenol to remove impurities and then subjected the refined rosin to vacuum-distillation for further purification.<sup>54</sup>

Humphrey<sup>55</sup> removed coloring matter by condensing rosin with an aldehyde and ammonia or with hexamethylenetetramine and distilling the product under reduced pressure. A similar procedure was described by Zilberman and others.<sup>56</sup> A condensation product is formed by heating 100 parts of rosin for 24 hours with 25 parts of 40 per cent formaldehyde solution and 0.1 part of hydrochloric acid.

Fig. 120.

Illustrating the Clarity of Wood Rosin  
(O. A. Pickett and J. M. Schantz.)

Courtesy Industrial and Engineering Chemistry

This product is distilled at 300°C. under reduced pressure to recover pure colophony.

The process used by Hey<sup>57</sup> consists in dissolving rosin in an organic solvent and submitting it to the action of zinc and hydrochloric acid. The rosin solution is placed in a container having one wall made of zinc provided with small perforations, and this container is immersed in an aqueous hydrochloric acid solution containing zinc. The rosin solution passes through the perforations into the acid solution where it is thoroughly agitated and then allowed to rise to the surface.

Purification of rosin by means of hydrogenation was used by Henke.<sup>58</sup> A catalyst such as nickel is used in the process, and after its removal the hydrogenated product is distilled (250-300°C. under 10 mm. or less pressure) and an intermediate fraction is collected (70-75 per cent yield). An absorption of 90 per cent of the theoretical amount of hydrogen is possible if rosin is dissolved in amyl alcohol and a small amount of concentrated hydrochloric acid and treated at 145°C. with hydrogen under 7 atmospheres pressure.<sup>59</sup> Palladium is used as the catalyst in this case.

It was found by Palmer, Burda and Oliver<sup>60</sup> that the suggested use of fuller's earth in decolorizing rosin<sup>61</sup> did not apply very well in the case of wood rosin. Excessive amounts of earth had to be used because of the presence of terpenes which by partial polymerization cause gummy precipitates on the filter. In addition, the terpenes which do not polymerize act as solvents for the rosin impurities, preventing their adhesion to the fuller's earth. To remove the terpenes the rosin is distilled with dry steam at elevated temperatures. The residue is dissolved in a petroleum distillate (boiling 100-160°C.) and cooled to about 20°C. to precipitate petroleum-insoluble matter and is then filtered through fuller's earth. In one method of filtering a series of beds is used and as the first bed becomes saturated with impurities it is cut out of the group and is replaced by a fresh filter placed last in the series, each of the other filters then being advanced one position in the group.<sup>62</sup>

In a process used by Brooks<sup>63</sup> for purifying natural resins the crude material is mixed with a chlorohydrin of a gaseous olefin (e.g., ethylene- or propylenechlorohydrin) to form a thin viscous mixture. A temperature of 60-70°C. is normally employed. The proportion of resin to chlorohydrin is usually 1 to 5. Impurities are removed by filtration and the resin is recovered by vacuum-distillation of the chlorohydrin. Tournel<sup>64</sup> converted rosin into potassium resinate in order to separate impurities. The rosin (1 part) is powdered and suspended in 3 parts of water which is then heated to boiling and treated with 1 part of caustic potash solution (sp. gr. 1.33). When a pasty consistency has been obtained 8 parts of water are added and the boiling is continued for 15 minutes. The resinate is coagulated with an electrolyte and the supernatant liquid containing the impurities is siphoned off. The resinate is again suspended in water and is treated with sodium carbonate and a small amount of sodium peroxide (1 per cent). The boiling is continued and the resinate is recoagulated with sodium chloride and hydrochloric acid.

In order to obtain a rosin which would not tend to crystallize, Palmer<sup>65</sup> treated wood rosin in naphtha solution with sufficient caustic alkali to neutralize from 3 to 6 per cent of the abietic acid in the rosin. A reduction in crystallizing tendency and an improvement in color results when rosin is subjected to a heat treatment (280-350°C.) for half an hour in an inert atmosphere such as carbon dioxide.<sup>66</sup> By heating wood rosin at 260-325°C. Logan<sup>67</sup> effected a reduction in the crystallization tendency and at the same time increased the optical rotation.<sup>68</sup> It appeared that the alteration in optical rotation is directly proportional to the lowering of the crystallization tendency. By heating wood rosin at 300°C. for two hours the optical rotation changes from +4 to about +25. At the same time the discoloring impurities are made soluble in rosin solvents. It was later found that this same treatment removes what are designated "potential color bodies" from rosin which has already been bleached.<sup>69</sup> Although bleached rosin appears to be free of coloring matter it tends to develop a yellowish color when converted into an alkali soap

and precipitated with aluminum salts. This is of course objectionable if the material is used in sizing paper.

It was stated by Humphrey<sup>70</sup> that a composition which will not crystallize can be produced by mixing rosin with about 15 per cent or less of a rosin-distillation residue. This mixture can be used in core oils, varnishes and printing inks.

### LIMING OF ROSIN

Untreated rosin is unsatisfactory for use in varnishes directly for many reasons. It is too soft and is neither waterproof nor durable. If a solution of rosin in benzene is brushed out on a surface the resulting film when dry will attain a high gloss, but in a short time it will become dull. In warm weather the film will become sticky, possessing what is known as the printing effect. In damp weather there will appear on the film a bluish opalescence or "bloom," evidently caused by surface-absorption of moisture by the resin acid. All these qualities are to be found in varnishes containing rosin as such in considerable quantities. Rosin is used to a small extent to assist the solution of natural gums and fossil resins, but the temptation to use larger proportions is great because of its relative cheapness.

Another objection to the acid nature of rosin is its influence on the "livering" of varnishes, a peculiar thickening which occurs when basic pigments are ground with varnishes. Thickening is due principally to colloid reactions causing molecular aggregation and gel formation.<sup>71</sup> The rate of living increases with the acidity of the varnish.<sup>72</sup>

It was discovered long ago that rosin becomes harder and less sticky by partial neutralization with lime.<sup>73a</sup> Rosin so treated is known in industry as "lime-hardened rosin," "limed rosin" or simply "hardened rosin." A hardened rosin varnish will hold its gloss longer than one from ordinary rosin.

The customary method of liming rosin is by fusion. Complete neutralization cannot be effected in this manner, nor is it desirable. A completely or nearly completely neutral lime soap is only partially soluble in the common varnish oils and solvents. In the treatment of rosin with lime a purely neutral resinates is not formed, but rather a mixture of neutral and basic resinates, so that the acidity does not decrease in direct proportion to the amount of lime used. The ratio of basic to neutral resinates appears to increase with the amount of lime, and at the same time there is formed in the fused mass a suspensoid of hydrated lime which decreases the fusibility of the batch. Under these conditions the temperature

It has been stated, however, that thickened paints and varnishes can be restored by the addition of 0.5-10 per cent of free fatty acids. See T. F. Bradley, U. S. P. 1,478,017, Dec. 18, 1923, *J.S.C.I.*, 1924, 43, 224B.

<sup>72</sup> Although monobasic acids frequently increase the rate of living of varnishes it has been reported that tribasic acids, e.g., boric or phosphoric reduce living in some cases. See Schulmann, *Farbe u. Lack*, 1934, 307; *Brit. Chem. Abs.*, B, 1934, 725.

<sup>73a</sup> The use of lime for hardening rosin was advocated in 1884 by A. K. Kissel (U. S. P. 303,436, Aug. 12, 1884, to C. Zimmer. Reissue 10,714, Apr. 20, 1886. U. S. P. 414,366, Nov. 25, 1890. British P. 8036, 1884; German P. 30,000, 1884; French P. 162,098, 1884). Other bases were suggested also by Kissel, for instance, baryta or magnesia. J. B. Melvin (U. S. P. 370,640, Sept. 27, 1887; British P. 5270, 1886; *J.S.C.I.*, 1886, 3, 432) recommended zinc oxide and other metallic oxides. Carleton Ellis and H. M. Weber (U. S. P. 1,381,863, June 14, 1921; *Chem. Abs.*, 1921, 15, 3586) used calcium cyanamide. The use of 25-30 per cent of calcium acetate was suggested by M. Bottler (*Kunstst.*, 1913, 3, 84; *Chem. Abs.*, 1913, 7, 2314).

needed to liquefy the mass is so high that decomposition of the resinates occurs. For these reasons complete neutralization of rosin cannot be carried out by the fusion method. A pale, hardened rosin will not have much less than 30 per cent free rosin acid.<sup>73</sup>

For the liming operation a good grade of hydrated lime technically free from iron and containing less than 1 per cent of magnesium oxide should be chosen. Iron is objectionable because of the dark colors it imparts, and magnesium decreases the solubility of the product. Magnesium resinates have a greater viscosity than those of calcium resinate so that the presence of the former causes thickening of varnishes. Hydrated lime is preferred to quicklime because of its more flocculent condition, permitting it to react more readily with the rosin.<sup>74</sup> Also, in the reaction of hydrated lime with rosin, steam is evolved which serves to keep the lime in suspension, whereas quicklime will tend to settle to the bottom.<sup>75</sup>

A tentative specification made by Gardner<sup>76</sup> for hydrated lime to be used in varnish is: color, white; fineness, not more than 10 per cent over 250-mesh; reactivity, satisfactory in gloss-oil and tung-oil tests; calcium oxide, not less than 70 per cent (equivalent to 92.5 per cent calcium hydroxide); magnesium oxide, not more than 3 per cent; insoluble matter and oxides of iron and aluminum, not more than 2 per cent; carbon dioxide, not more than 2 per cent.

In ordinary practice the maximum amount of lime used is 6-8 per cent of the weight of rosin, the acid number of the rosin being reduced from 165 to 70 with 6 per cent of lime.<sup>77</sup> With this amount a transparent product should be obtained, but with higher percentages a cloudy effect is produced. Also, as was stated previously an overlimed rosin is not completely soluble in varnish oils and solvents. Therefore ordinarily 5-6 per cent of lime is used. The customary procedure is to heat the rosin to 300°C. to prevent crystallization, cool to 200°C. and stir in the lime gradually. Although ordinarily the lime is added dry it is said that somewhat better results are obtained by mixing it with a little linseed oil and water and adding 0.1 per cent calcium or lead acetate as a catalyst.<sup>78</sup> The temperature is then raised to 260°C. and the mixture is stirred to prevent settling of the lime. After all the lime has been taken up and the water has been driven off the rosin is poured into cooling pans. In order to get the best control of color and acidity large batches are cooked in closed kettles under careful supervision.

In the hardening of rosin other basic oxides are sometimes used in place of or in addition to lime.<sup>79</sup> For instance a grinding-varnish rosin is made by hardening rosin with 2 per cent of magnesium oxide and 5 per cent zinc oxide. The use of 4 per cent of slaked lime and 2-3 per cent of zinc oxide gives a rosin for rubbing-varnishes.<sup>80</sup> The method employed is to add zinc oxide at 220-240°C., continue

<sup>73</sup> A. Murray, *Chem. Met. Eng.*, 1921, 25, 473.

<sup>74</sup> The use of hydrated lime and of carbonate of lime and calcium sulphide in place of quicklime for hardening rosin was recommended by S. Banner (British P. 11,805, 1887; *J. S. C. I.*, 1888, 7, 573). The amount of hydrated lime used was 3-15 per cent. In some cases 3-7 per cent sulphur was used, the amount of lime then being reduced. See also C. Cofignier, *Chimie et industrie*, 1921, 5, 497; *Chem. Abs.*, 1921, 15, 2555.

<sup>75</sup> Manufacturers formerly favored the use of oyster-shell lime because although its calcium oxide content is comparatively low it is technically free from magnesium and iron salts and its composition is reasonably constant. The use of coral lime was recommended by W. H. Scheel (U. S. P. 1,428,120, Sept. 5, 1922, *Chem. Abs.*, 1922, 16, 3766).

<sup>78</sup> See J. M. Schantz, *Paint. Oil, Chem. Rev.*, 1931, 92 (17), 9; *Chem. Abs.*, 1932, 26, 609. An organic carboxylic acid (particularly acetic), a halogen or a halogen acid or salt has been suggested as catalyst by E. V. Romaine, H. J. Weiland, P. O. Bowers and R. C. Palmer (U. S. P. 1,884,407, Oct. 25, 1932, to Newport Industries, Inc.; *Chem. Abs.*, 1933, 27, 1163).

<sup>79</sup> See O. Prager, *Seifen. Ztg.*, 1915, 42, 686, 705; *Chem. Abs.*, 1915, 9, 3369. In using metallic oxides pale-colored products are obtained if the oxides are in a finely divided state. See Krumbhaar, *J. Oil. Col. Chem. Assoc.*, 1934, 17, 413; *Brit. Chem. Abs. B.*, 1935, 160.

<sup>80</sup> F. Pirschel (U. S. P. 521,270, June 12, 1894) stated that by using rosin oil as a flux as much as 16 per cent of manganese dioxide, 10 per cent of barium oxide or 40 per cent of lead oxide could be absorbed by rosin.

heating until the mixture is clear, then add slaked lime and raise the temperature to 275°C. to complete the reaction.<sup>81</sup>

Natural resins other than rosin have been hardened with lime although such treatment renders them partially insoluble in turpentine or linseed oil and lowers their resistance to the action of water and the atmosphere.<sup>82</sup> Resins treated in this way include dammar and various copals such as Manila, kauri, Congo, Zanzibar and Hymenaea (S. American).

Similarly, the melting point of crude montan wax is raised by heating the wax with about 1 per cent of a metal hydroxide, basic oxide or carbonate in water at temperatures between 100°C and the melting point of the wax.<sup>83</sup> The treatment may be effected also by dissolving the wax in an organic solvent in which case the reaction is carried out at temperatures up to 200°C.

**Gloss Oil.** If lime-hardened rosin is dissolved in petroleum naphtha a very cheap variety of varnish is obtained. In industry this solution is known as "gloss oil," since it imparts a gloss to paints and varnishes in which it is used. Gloss oil is used to some extent in flat-white enamels and in cheap lacquers, tool varnishes, shingle stains and the like. Because of the free acid in gloss oil there is risk of yellowing<sup>84</sup> when it is used in flat-white paints, and when used in the priming coat for plaster or cement walls it ultimately causes crumbling.

Gloss oil may be prepared directly by melting rosin at about 150°C., thinning it with about an equal weight of mineral spirits and then adding the required amount of lime. The heating is continued at 110°C. until the lime has reacted, then the temperature is raised to 150°C. to remove water. Gloss oils prepared in this way using 10 per cent or less lime were still clear after 2 years aging.<sup>85</sup> In cases in which 12 per cent of lime had been used crystallization occurred.

A gloss oil, pale in color, was prepared by Davidson<sup>86</sup> by grinding the ingredients together in a pebble mill. It is stated that more lime can be introduced into rosin by this method than is used in the kettle method. If a varnish or enamel is to be made the pigment is ground with the rosin, lime and naphtha, and the other ingredients are added later.

Rosin and lime-hardened rosin are used extensively with tung oil (China wood oil) for the manufacture of varnishes. The characteristics of tung-rosin varnishes are pale color, rapidity of drying, high gloss, durability and waterproof qualities. A dried coating of gloss oil will promptly turn white on contact with water, and the same is true of a rosin-linseed oil varnish, although to a lesser degree.<sup>87</sup> A tung oil-rosin varnish, however, is highly resistant to water. Moreover, rosin acts as a good solvent for over-heated or gelatinized tung oil, and it has a retardant action on the polymerization of tung oil.<sup>88</sup> The use of lined rosin in place of raw rosin makes a harder and more quickly drying varnish but at the same time imparts brittleness.

Although some varnishes of this type consist simply of tung oil, rosin and thinners, others contain in addition linseed oil<sup>89</sup> or other oils and resins.<sup>90</sup> Con-

siderable study has been made on the cause of blooming in varnish films.<sup>91</sup> Krumbhaar<sup>92</sup> stated that a linseed oil-rosin varnish must contain at least 3 parts of oil to 2 of rosin to be free from bloom. According to Harrison and Fonrobert<sup>93</sup> factors which may produce blooming are excessive amounts of driers and free acids, certain thinners, improperly refined or cooked oils and improperly run resins. It has been pointed out that the presence of too much lime-hardened rosin will also cause blooming.<sup>94</sup>

#### VARIOUS METHODS OF HARDENING ROSIN

In addition to liming, other methods of hardening rosin have been devised.<sup>95</sup> Many of these include oxidation by various means.<sup>96</sup> One of the earliest consisted merely in passing a current of air or oxygen through molten rosin.<sup>97</sup> Another method is to use this same treatment with the addition of 1 to 5 per cent of a phenol or phenol ester which is said to impart toughness. A variation of this method consists in heating rosin with a ferric salt and hypochlorites.<sup>98</sup>

Schaal<sup>99</sup> passed a current of heated air or oxygen over powdered rosin, the temperature being kept below the melting point of the rosin.<sup>100</sup> The oxidized product is not soluble in oil of turpentine and fatty oils, and thus resembles fossil resins in that it must be heated above its melting point to render it soluble. In a modification of the Schaal process the powdered rosin (100 parts) is mixed with cobalt acetate (0.3 part) and anhydrous sodium sulphate (40 parts) and treated as described above.<sup>101</sup> The cobalt acetate can be replaced by either manganese resinate or manganese borate and a mixture of equal parts of sodium chloride and sodium sulphate can be used instead of the latter alone. After the hardening process the rosin is washed well with warm water and dried by slight melting or fusing.

It was observed by Miles<sup>102</sup> that the mere exposure of powdered rosin to air produces only slow oxidation probably caused by a film of inert gas on the rosin surface preventing the access of fresh oxygen. This difficulty is removed by moistening the rosin with water. The powdered rosin can be treated with a solution of hydrogen peroxide or it can be agitated with water and treated with ozone. The oxidation is promoted by mixing with the rosin such substances as calcium hypochlorite, formaldehyde, dilute sulphuric or sulphurous acid, milk of lime, soda ash and turpentine.<sup>103</sup> It was stated that rosin oxidized in this manner yields when

neutralized with ammonia a soap which is quite soluble in water. This rosin-ammoniate is used for coating various materials (e.g., paper). Whipple<sup>104</sup> improved the electrical insulating properties of rosin by passing moist air through molten rosin at 135°C. and then treating the melt at 140°C. with dry air. Other methods<sup>105</sup> of oxidizing rosin include passing air or oxygen or ozonized air into solutions of the material in non-aromatic hydrocarbons<sup>106</sup> or such solvents as glacial acetic acid.<sup>107</sup> Pungs<sup>108</sup> oxidized mixtures of waxes and rosin by passing heated air (160-170°C.) through the mixture in a retort charged with inert heat-conducting material.

In connection with the oxidation of rosin the observations of Korotkov and Rufinski prove interesting. Rufinski<sup>109</sup> found that the melting point of rosin is raised at least 12 degrees by blowing air through the molten rosin at 130-150°C for 10 hours and that the addition of 1 per cent calcium oxide and blowing at 200-212°C. for 6 hours raised the melting point of rosin to 107°C. The investigations of Korotkov<sup>110</sup> show that the ability of rosin to absorb oxygen spontaneously<sup>111</sup> depends on the temperature of its preparation from crude turpentine gum. The most stable rosins are prepared at 200-270°C. The oxidation of rosin decreases the iodine number 74-78 per cent and the acid number 12-18 per cent. In the opinion of Scheiber<sup>112</sup> the variations in the solubility of rosin in benzine are caused by the presence of products of auto-oxidation.<sup>113</sup>

One of the uses suggested for oxidized rosin is as a solvent for nitrocellulose in lacquers.<sup>114</sup> A similar application is in a shellac substitute composed of oxidized rosin, cellulose esters and camphor or camphor substitutes.<sup>115</sup> Oxidized rosin has been used as an anti-coagulant in linoleum manufacture.<sup>116</sup>

It may be of interest to note here certain products obtained by the oxidation of substances similar to rosin. Among these are a thermoplastic material procured by oxidizing the semi-fluid resin occurring in crude gutta-percha and balat.<sup>117</sup> and a resinous mass produced in the oxidation of turpentine oils<sup>118</sup> and pine-tar oils.<sup>119</sup>

Rosin was hardened by Low<sup>120</sup> by treatment with formaldehyde under pressure. This treatment applies also to other natural resins such as Manila copal and dammar gum. The method employed is to place rosin and 40 per cent formaldehyde solution in a closed reaction-vessel and then heat the mixture. An alternative procedure is to place rosin in a closed vessel and lead into the container vapors of formaldehyde and steam. The best results are obtained with 2-6 hours heating at 120-150°C. under 75-150 pounds pressure. The condensation of rosin and of other resins with formaldehyde was carried out in alcoholic solution by Lingner,<sup>121</sup> using an acid catalyst, e.g., hydrochloric, sulphuric, formic or acetic acid. As an example rosin (1 part) is dissolved in 4 parts of alcohol and mixed with 1 part of 40 per cent formaldehyde solution. Then hydrochloric acid is introduced into the mixture, causing the precipitation of the condensation product. This product has a higher melting point than the original rosin. The condensation of rosin with aldol or with crotonaldehyde using an acid condensing agent and a solvent such as benzene, carbon tetrachloride or trichloroethane was suggested by Balle and Giloy.<sup>122</sup>

Rosin can be condensed with aldehydes and ketones in the presence of alkalis, alkali sulphides or alkali carbonates.<sup>123</sup> Similarly Voss<sup>124</sup> condensed oxidized rosin with aldehydes. For instance, 200 parts of rosin are oxidized with oxygen under pressure at 100-200°C. and then mixed with 70 parts of formaldehyde and 40 parts of concentrated sodium hydroxide solution at 90-100°C. The mixture is heated 6-8 hours at 160°C. and then poured into a dilute alkaline solution, filtered and cooled. The product is precipitated with hydrochloric acid and then washed and dehydrated.

Boorne and Budde<sup>125</sup> suggested the use of metal oxides or hydroxides as catalysts in the condensation of rosin and aldehydes to form a product for molding articles.<sup>126</sup> In one instance rosin is condensed with formaldehyde using calcium oxide as catalyst, and the reaction product is mixed with sawdust, portland cement, petroleum and calcium carbonate.<sup>127</sup>

Amann<sup>128</sup> condensed formaldehyde and rosin by heating them together at temperatures below 135°C. (usually 110-120°C.) and then modified the product by treating it with phenol or by melting together a phenol-aldehyde resin and the rosin-formaldehyde resin.

A process for simultaneously bleaching and hardening dark-colored rosin was devised by Stuhlmann.<sup>129</sup> The rosin is dissolved in a cold, dilute alkali solution

<sup>129</sup> P. Stuhlmann, U. S. P. 1,809,738, June 9, 1931; *Chem. Abs.*, 1931, 25, 4423. British P. 289,859, 1928, to C. Cordes A.-G.; *Brit. Chem. Abs. B*, 1929, 826.

which is kept in continuous motion by a stirring device. The bleaching agent and the aldehyde are then added, reaction taking place in the cold. The product was suggested for sizing paper. The condensation of rosin with a primary aromatic amine yields a product said to be useful as a vulcanization accelerator.<sup>130</sup> An adhesive for fastening rubber to metal or glass is made by condensing aldehydes with the resins from balata or gutta-percha.<sup>131</sup>

The condensation of colophony with phenols in acid solution yields yellow- to brown-colored resins insoluble in water but soluble in alkaline solutions. The sulphonation of these products and conversion into alkali salts yields water-soluble tanning agents.<sup>132</sup> As an example 30 parts of rosin and 15 parts of phenol are heated with 1.5 parts of sulphuric acid (specific gravity 1.7) for 8 hours at 70-80°C. The resulting condensation product is dissolved in carbon tetrachloride and sulphonated with sulphuric acid monohydrate at 10°C. The sulphonated mass is dissolved in hot water and then salted out.

The halogenation of rosin produces a hardening effect but at the same time renders it insoluble in petroleum ether.<sup>133</sup> The chlorinated product is soluble in benzene, alcohol and turpentine, however. To form a product containing 5.5 per cent chlorine, a solution of 200 parts of rosin in 2000 parts of an alkaline solution (containing 19.5 parts sodium hydroxide) is treated with 40 parts of chlorine. The precipitated resin is filtered off, washed and dried. One of the uses for chlorinated rosin is as a soldering flux.<sup>134</sup>

Many methods have been devised by Auer for modifying the properties of rosin and similar substances to form materials for use in varnishes, linoleum and rubber substitutes. In one of these<sup>135</sup> rosin is dissolved in an organic solvent and heated with an electrolyte. Further modification is brought about by vulcanization with sulphur or a sulphur compound. In another method rosin is heated under reduced pressure with a modifying agent consisting of a small proportion of formic acid mixed with such salts as ammonium iodide, sodium sulphide, zinc carbonate or magnesium sulphate.<sup>136</sup> Alkaline oxides or hydroxides are dissolved in rosin and treated with peroxides in one procedure<sup>137</sup> and in a further procedure rosin is heated with sulphur chlorides or sulphonic acids.<sup>138</sup>

Hardened natural resins have been used in a great many ways, only a few of which are mentioned here. The use of hardened rosin as a substitute for copal in plastics of sulphur and resin was suggested by Kissel.<sup>139</sup> A binding medium for roofing is formed by mixing hardened rosin with rosin oil or a heavy mineral oil and adding fillers and waxes.<sup>140</sup> An insulating material can be made from a mixture of creosote oil (8-12 parts), shellac (8 parts), rosin (4 parts), alum (0.5 part) and various amounts of asbestos, magnesium carbonate and calcium hydrox-

ide.<sup>141</sup> Another insulating mixture is made from linseed oil, copal, zinc oxide and sulphur.<sup>142</sup> This mixture is exposed to the air 5-9 days and then molded and baked at 50-120°C. Shellac which has become infusible and alcohol-insoluble is reconditioned for use in varnishes and adhesives by mixing it with rosin at 270°C.<sup>143</sup> A composition stated to be a good shellac-substitute was obtained by Dietz and Oeffinger<sup>144</sup> by heating a mixture of batu gum (18-20 parts) and rosin (10-20 parts) with quicklime (1-4 parts) at 260°C. A water-resistant cement for tools is made by fusing hardened rosin with neutral resins and fillers.<sup>145</sup> For making artificial stone or cellular concrete, rosin is mixed with casein or glue and with a cementitious material to produce a foam and then allowed to set.<sup>146</sup>

A molding material is formed by mixing powdered rosin with gasoline or other petroleum fractions and adding milk of lime.<sup>147</sup> The solid product is molded under pressure and is hardened by immersion in water containing gallic acid. For preparing an insoluble product which is resistant to a high temperature and is moldable, shellac was heated at 120-280°C. with 7-10 parts of zinc oxide.<sup>148</sup> A gelatinous material suggested as a belt dressing is formed by mixing kerosene with the reaction product of lime, rosin, formaldehyde, ammonia and chlorinated lime and neutralizing with acetic acid.<sup>149</sup> An artificial asphalt is made by mixing together rosin, shellac, lampblack and a wax.<sup>150</sup> Rosin mixed with montan wax, gilsonite and other materials including fibers forms a box-toe composition.<sup>150</sup>

Banner<sup>151</sup> prepared a linseed-oil substitute by dissolving rosin in a solvent and saponifying it with 18 per cent (of the weight of rosin) of potassium or sodium hydroxide. A turpentine substitute was prepared by Odom<sup>152</sup> by heating rosin with 10 per cent of its weight of calcium oxide for 2 hours at 190°C. and then adding a petroleum distillate and distilling the mixture. Shine<sup>153</sup> made a paint containing a natural resin and old rubber as follows: The scrap rubber is devulcanized, fused and mixed with fused resin and hydrated lime. The mixture is treated with a rubber solvent and with about 10 per cent of its weight of zinc sulphate.

### ROSIN OIL

The destructive distillation of rosin yields a viscous oil known as rosin oil, which is used in the manufacture of lubricants, printing inks, varnishes, cable insulation, oilcloth and linoleum, transformer oils, brewer's pitch and similar materials.<sup>154</sup> The commercial preparation of rosin oil has been described by Grotlich.<sup>155</sup>

<sup>155</sup> It may be of interest to note the results of the destructive distillation of other resins, for instance the copals. See A. H. Gill and D. Nishida, *Ind. Eng. Chem.*, 1923, 15, 1276, and H. Wolff, *Farben-Ztg.*, 1924, 29, 2039; *J.S.C.I.*, 1924, 43, 952B.

<sup>156</sup> V. E. Grotlich, *Proc. Am. Soc. Testing Materials*, 1930, 30(2), 834; *Chem. Abs.*, 1931, 25, 2309. See also H. Hadert, *Farben-Chem.*, 1934, 5, 130; *Chem. Abs.*, 1934, 28, 3603.

The distillation is carried out in cast-iron or steel stills holding 6500-12,000 pounds of rosin. The darker grades of rosin are usually employed. Water is first evolved (at about 120°C.), then various fractions of rosin oil are collected. These fractions are rosin spirits (pinohn) (160°C.), light oil (200°C.), kidney oil (250°C.) and bloom oil (270°C.). Distillation is stopped at 360°C., leaving a residue of rosin pitch. Kidney oil, the most valuable fraction, is used principally in greases and printing inks. Because of its acid content (40-56 per cent) the kidney oil is converted partially into soaps when used in greases.

One of the early methods of rosin oil production consisted in heating rosin in an iron autoclave at 250-260°C. under 12-15 atmospheres pressure.<sup>166</sup> In one of the modern methods rosin is heated at 150-325°C. (300°C. is considered best) with 2 per cent of a siliceous earth or of activated carbon, yielding a neutral rosin oil.<sup>167</sup>

Binapff<sup>168</sup> used in a similar process a catalyst composed of an aluminum hydro-silicate activated with hydrochloric acid. To illustrate, 500 parts of rosin are heated with 25 parts of catalyst to a temperature of 180-200°C. in one hour. Heating is continued for another hour at 215-220°C. When the evolution of gases has ceased the temperature is raised to 240-250°C. for 20 minutes. The catalyst is removed by filtration and the product is distilled *in vacuo* yielding a clear, yellowish oil (boiling 70-390°C.) and leaving a small amount of pitchy residue. The oil is substantially neutral (acid value less than 1), consisting mainly of hydrocarbons.

In a process devised by Hoge<sup>169</sup> rosin is subjected to a vapor-phase cracking at 370-590°C. under atmospheric pressure to yield liquid products. Aluminum is used as the catalyst in the cracking. Fractionation of the liquid products yields materials for various uses. For instance, a fraction from 75-160°C. is used as a gum solvent in lacquer manufacture and one from 190-250°C. is proposed as a plasticizer in lacquers. A light, oily product said to be useful in paints is obtained by heating a rosin and water mixture to above 480°C. so that a vapor pressure of 5000 pounds per square inch is produced.<sup>160</sup>

Johnston<sup>161</sup> obtained a drying oil (b.p. 340-360°C.) by heating rosin with benzenesulphonic acid at 250-300°C. and removing the oil by distillation. The product is rendered neutral by redistilling from dilute sodium carbonate solution.

The distillation of rosin or other natural resins with 1-5 per cent of phosphoric acid up to 310°C. yields a light oil (50 per cent yield) useful as a turpentine substitute. The still-residue is a neutral rosin oil of low viscosity.<sup>162</sup> In other methods of rosin-oil production, rosin is distilled with boric acid or a borate<sup>163</sup> (0.05-1.0 per cent) or with zinc chloride.<sup>164</sup>

Some idea of the nature of rosin oil formation can be obtained from the studies

of Easterfield and Bagley,<sup>165</sup> Ruzicka and Schinz<sup>166</sup> and La Lande.<sup>167</sup> An unsaturated hydrocarbon,<sup>168</sup> abietene, results from the decarboxylation of abietic acid by one of the following reactions:

The sulphonation of abietene yields a product useful as a wetting agent.<sup>169</sup> Abietenesulphonic acid is a black paste soluble in water in all proportions, and its sodium salt, which is usually employed as the wetting agent, is described as a tan-colored powder.

Products for varnishes can be obtained by the oxidation of rosin oil.<sup>170</sup> An oil boiling above 200°C. is treated under reflux with a current of air containing 10-15 per cent of superheated steam until it becomes nearly solid. Distillation of the product yields 20-30 per cent of unchanged oil, 30-40 per cent of heavy rosin oil and 30-40 per cent of black pitch. Bedford and Bedford<sup>171</sup> oxidized rosin oil to a viscous mass useful in linoleum manufacture. It has been reported, however, that a very brittle product results when this is used.<sup>172</sup>

#### RESINS FROM TERPENES

Turpentine, pine oil and related materials are potential raw materials for synthetic resins and can be considered here since they are derived from the same source as rosin. The principal constituent of turpentine is a terpene, pinene, and of pine oil is a mixture of terpene alcohols (largely  $\alpha$ -terpineol) with small amounts of terpene hydrocarbons and ethers.<sup>173</sup> As has been mentioned previously, pine oil is obtained by steam-distillation of pine wood. In addition to the recovery of pine oil and turpentine in this process other terpene hydrocarbons such as limonene, dipentene, terpinene and terpinolene are also obtained as intermediate fractions.<sup>174</sup>

The principal methods for producing resinous materials from these substances are by oxidation or by polymerization. In fact turpentine tends to resinify during storage, probably because of oxidation.<sup>175</sup> The evaporation of turpentine and pine oils in open vessels yields resinous materials as a result of oxidation and polymerization.<sup>176</sup> Thickened turpentine obtained in this manner is known commercially as

"fat oil." Experiments performed by Horton and McCormick<sup>177</sup> on laboratory-made fat oil indicated that the oil can be used in cellulose lacquers in amounts up to 25 per cent. It was stated that hard films of high natural gloss and of satisfactory resistance to steam and ultraviolet light are obtained with such lacquers.

Gardner<sup>178</sup> polymerized turpentine to obtain a paint vehicle which forms a hard surface on drying. In the procedure turpentine or pine oil (100 parts) is heated at 80-160°C. with 92 per cent sulphuric acid (5-7.5 parts). The polymerization of turpentine hydrocarbons with sulphuric acid yields substances suggested for use in the rubber and varnish industries.<sup>179</sup> The acid is stirred into the oil of turpentine until 20 per cent of the mixture is acid and then heat is applied. The method may be varied somewhat by adding 5-10 per cent of potassium dichromate to the acid.

The conversion of turpentine and pine oils into heavy paint-vehicles was carried out by Smith<sup>180</sup> by refluxing the oil in contact with fuller's earth. The earth is placed between the still and the reflux condenser so that both the vapors and the returning condensate will come in contact with it. The polymerization of turpentine can be effected by prolonged heating either alone or with aluminum chloride, aluminum bromide or zinc chloride.<sup>181</sup> Cooper<sup>182</sup> obtained a drying oil by treating a turpentine solution with aluminum chloride at 30°C. and distilling the product under reduced pressure.

Various methods were used by Humphrey<sup>183</sup> to polymerize turpentine, pine oil and dipentene. In one of them the vapors of pine oil are brought into contact with fuller's earth for 8 hours at 160-170°C. In another process dipentene vapors are passed in intimate contact with fuller's earth, aluminum oxide or chlorides of zinc, tin, aluminum or iron at 400°C. The oils themselves are heated with fuller's earth or metallic chlorides in other procedures. A turpentine substitute is made by heating pine oil with iodine and then steam-distilling. To produce a rapidly drying oil, a polymerized terpene product from turpentine, pine oil or dipentene is distilled to remove the fraction boiling below 335°C. so that only polymers higher than the diterpene are retained.<sup>184</sup>

A drying-oil substitute can be prepared by heating pine-tar with salts of lead, manganese or copper to above 150°C. and then diluting the product with an organic solvent.<sup>185</sup> To form a binder for printing inks polymerized terpenes are mixed with boiled wood oil.<sup>186</sup> Another use of polymerized terpenes is in the formation of adhesives by mixing them with natural gums.<sup>187</sup>

It has already been mentioned that the oxidation of turpentine and pine oil causes resinification.<sup>188</sup> Pellnitz<sup>189</sup> resinified pine oil by adding to it 1 per cent of acetic or resin acid and treating with moist, ozone-containing air under pressure.

The product formed is treated with quicklime and steam-distilled. The oxidation of turpentine with air or oxygen in the presence of a catalyst produces a fatty essence.<sup>190</sup> A drying oil which may be used as a substitute for linseed oil was made by Rankin<sup>191</sup> by treating dipentene with ozone at temperatures below 110°C. Heating the product to 120°C. increases its solvent power for nitrocellulose but decreases its drying power. Another drying oil is obtained by first polymerizing turpentine oil or dipentene by refluxing it with sulphuric acid or stannic chloride and then treating the product with ozonized air.<sup>192</sup>

Humphrey<sup>193</sup> produced an oil capable of assisting the dissolving of nitrocellulose by treating pine oil with a dehydrating agent and then oxidizing the product. The object of the dehydration is to convert terpineols into lower-boiling substances thus giving greater volatility and better solvent action to the oil. As an example pine oil is heated with 1.5 per cent of fuller's earth for 1 hour at 145°C. The earth is removed and the oil is fractionally distilled. The higher-boiling fraction is oxidized with nitric acid, chromic acid, chlorine or other agents and then mixed with the lower-boiling fraction. From 1 to 20 per cent of this product is incorporated in nitrocellulose lacquers.

Resins were produced by Orlov<sup>194</sup> by condensing turpentine with formaldehyde. As an example 200 parts of sulphuric acid (specific gravity 1.84) are mixed slowly with 100 parts of turpentine. To this are added 55-65 parts of 40 per cent formaldehyde solution at a temperature below 40°C. The mixture is allowed to stand for 12 hours and is then neutralized with ammonium hydroxide, producing a green coloration. The aqueous layer is removed, the residue is given a further treatment with ammonium hydroxide and the mixture is heated to boiling and then allowed to cool. The resin obtained (80 per cent yield) by filtration and drying (70-80°C) is yellowish brown in color and is soluble in alcohol, ether, benzene, toluene, acetic acid, ethyl acetate and solvent naphtha. Solutions with the last two of these give quick-drying lacquers.

In like manner reaction takes place between pine oil and paraformaldehyde as shown by the following experiment performed in the author's laboratory:

A mixture of 50 grams of pine oil, 15 grams of paraform and 20 cc. of concentrated hydrochloric acid was heated under a reflux condenser. After the paraform had passed into solution an additional quantity of 15 grams was added and the refluxing continued. All of the paraform dissolved but the odor of formaldehyde persisted. The solution became very dark brown in color and considerably thicker. The reaction product did not separate easily from the aqueous acid, hence it was extracted with benzene. After evaporation on the water bath a product of tarry consistency remained. When this was carefully heated to a somewhat higher temperature a portion volatilized and the remainder upon cooling solidified to a brittle brownish-black mass.

Ushakov and Sokolov<sup>195</sup> used the procedure of Orlov to obtain resins from pine oil. Borneol, camphane and pinene, obtained from the oil of Siberian fir, condensed with formaldehyde in the presence of sulphuric acid to yield pitches soluble in benzene. Bornyl and isobornyl chlorides, obtained from the fraction of this oil boiling between 156-162°C., when condensed with formaldehyde using ferric chloride or sulphuric acid as a catalyst, produced black or dark-brown resins.

Constituents of pine oil were used by Wuyts<sup>196</sup> in condensations with phenols to form resinous products. Catalysts employed included phosphoric, oxalic, sulphuric and halogen acids, chlorides of zinc, aluminum and iron, siliceous earths and halogens. The various products formed were suggested as antiseptics, as electric insulators and in the manufacture of varnishes. An emulsion with water in alkaline solution was found useful for degreasing and cleaning purposes.

As an example of such resin formation, equimolecular proportions of carvene and phenol were mixed with 0.1 per cent of p-toluenesulphonic acid and the temperature was maintained below 105°C. The reaction product was treated with steam and then with caustic soda or potash using toluene as a solvent. In this latter step two layers formed, and from the alkaline layer was recovered the resinous product.

The use of terpinene-maleic anhydride as an adhesive for uniting celluloid or other transparent material to glass in the making of safety glass was suggested by Peters.<sup>197</sup> The compound is produced by the reaction of 480 parts of  $\alpha$ -terpinene with 294 parts of maleic anhydride at 150-200°C. for 5 hours. Impurities are removed by distillation under vacuum (15 mm).

Many miscellaneous experiments with terpenes have yielded resins. For instance, pinene and oxalic acid react to form a large quantity of resin and a small amount of acetic acid.<sup>198</sup> Treatment of pinene with phosphorus pentachloride yields hydrogen chloride, pinene dichloride, phosphorus trichloride, some tar and a dark yellow resin.<sup>199</sup> An adhesive for catching insects has been prepared from chlorinated terpenes.<sup>200</sup> Prolonged contact of turpentine with iron yields small amounts of a clear, red resin.<sup>201</sup> Resinous material is formed in the oxidation of limonene with hydrogen peroxide in acetic acid solution.<sup>202</sup> Citral upon treatment with 50 per cent sulphuric acid yields p-cymene and resinous substances.<sup>203</sup>

Cedrenene,  $C_{15}H_{22}$ , tends to polymerize to an amorphous mass when placed in contact with acetic anhydride or when boiled at ordinary pressure.<sup>204</sup> When linalool is heated with aluminum at 160-205°C. there are formed dipentene (30 per cent), camphor (2 per cent), borneol (0.8 per cent), camphorene (22 per cent) and resin (15 per cent).<sup>205</sup> The treatment of caryophyllene with ethyl diazoacetate yields a cyclopropane ester which on subsequent hydrolysis with concentrated caustic potash forms a resinous acid.<sup>206</sup> Pinocarveol and sabinol, when heated with aluminum alcoholate yield pinocamphone and sabinol tenacetone and resinous material as a by-product.<sup>207</sup> Attempts made by Houben<sup>208</sup> to esterify terpineol, linalool and geraniol by means of magnesium alkyl bromides produced colored halogen-containing esters which quickly resinified.

#### RESINATES AND OTHER METALLIC SOAPS

Although this discussion should adhere strictly to the metallic salts of resin acids, the salts of fatty acids and naphthenic acids will be considered to some extent because of the similarity of their uses. The term "metallic soap" applies

generally to the water-insoluble salts and therefore does not include soaps of the alkali metals. These metallic soaps have found extensive use in paints and varnishes, waterproofing materials, greases, emulsifying agents, wetting agents and plastic materials. As driers in paints the soaps of cobalt, manganese and lead are most commonly used.<sup>200</sup>

Metallic soaps are of two types, generally referred to as fused soaps and precipitated soaps. The fused soaps are made by heating free fatty or resin acids with metal oxides, substantially as described in the section on the liming of rosin. Precipitated soaps are prepared by the double decomposition of alkali soaps (sodium, potassium or ammonium) in aqueous or alcoholic solution with aqueous solutions of salts of the other metals.<sup>210</sup> The precipitated soaps are distinctly superior to those made by fusion because when properly prepared they contain a definite percentage of metal which completely saturates the acid employed, whereas the fused soaps are rarely definite in composition and the acid is only partly neutralized.<sup>211</sup> Preference is often given however to the fused soaps because of their ease of preparation.<sup>212</sup> It has been shown that the fused soaps show less tendency to crystallize and precipitate from solution because of their lower metal content.<sup>213</sup>

As has just been mentioned one of the uses for resinsates and other metallic soaps is as drying agents in paints and varnishes.<sup>214</sup> Many explanations of the action of driers have been made. In the modern theory of drier action the driers accelerate the oxidation of oils by neutralizing antioxidants and to a lesser degree accelerate association or polymerization of the oxidized oil molecules. Also, it is conceivable that the driers accelerate gelation of the oil by acting as coagulation nuclei.<sup>215</sup> The results of various investigations show that the most efficient driers

are the soaps of cobalt and manganese. These and the soaps of lead are the most commonly used driers.<sup>216</sup> It has been found that mixtures of metallic soaps produce more rapid drying action than the soaps of any one metal alone.<sup>217</sup> In the opinion of Steele<sup>218</sup> there is practically no advantage in the use of more than 0.05 per cent of either cobalt or manganese to dry linseed oil nor more than 0.05 per cent of lead in combination with 0.01 per cent of manganese or 0.1 per cent of lead with 0.005 per cent of manganese. It has been found that cobalt driers (oleate or resinate) exert a greater influence in causing "skinning" of stored varnishes than do the soaps of lead or manganese.<sup>219</sup> Much has been said about the relative efficiency of various soaps, some workers preferring oleates and linoleates and others advocating resinates.<sup>220</sup>

The use of naphthenates as driers in paints and varnishes has been recommended by various investigators<sup>221</sup> because of their uniformity, stability and better solubility.<sup>222</sup> These compounds, commonly known as Soligen driers, are metallic soaps of naphthenic acids, which are derived from crude petroleum.<sup>223</sup>

In one method of producing naphthenate driers, naphthenic acid is saponified with sodium or potassium hydroxide in a boiling aqueous solution. A salt of a

<sup>223</sup> Naphthenates are discussed more completely in Chapter 10. For a detailed treatment of this subject see Carleton Ellis, "The Chemistry of Petroleum Derivatives," The Chemical Catalog Co., New York, 1934.

heavy metal is then added and the resulting precipitate is washed by decantation. The product is dehydrated by fusion. To assist the fusion, plasticizers (castor oil, tolyl phosphate, cyclohexanone, etc.) are added during or following precipitation.<sup>224</sup> In another method of preparation naphthenic acid is mixed at ordinary temperature with weak-acid salts of metals.<sup>225</sup> Naphthenates are formed also by adding metallic oxides to a solution of naphthenic acid in an organic solvent.<sup>226</sup>

Concentrated, homogeneous solutions of naphthenate driers are produced by dissolving the naphthenates in drying or semi-drying oils or in their fatty acids.<sup>227</sup> The fatty acids may be replaced wholly or partially by unsaturated aliphatic or aromatic acids or by substituted benzoic acids.<sup>228</sup> The solubility of naphthenates in organic solvents is improved by fusion with not more than 10 per cent of a solid, saturated fatty acid containing 16-20 carbon atoms.<sup>229</sup>

Other metallic salts suggested as driers include those of o-keto-aromatic acids,<sup>230</sup> those of keto acids prepared from acid anhydrides and petroleum hydrocarbons<sup>231</sup> and those of benzoic acid derivatives in which a nuclear hydrogen atom has been replaced by a hydrocarbon radical.<sup>232</sup> It is stated that improved driers are formed by using the heavy-metal salts of acids of the general formula  $R-O-C_nH_{2n}-COOH$  in which R is either an alkyl group of more than 3 carbon atoms, a hydro-aromatic group or an aralkyl group.<sup>233</sup>

In the opinion of Zinoviev,<sup>234</sup> an ideal drier should have little effect on the color of the oil used, should not form a sediment, should dry in 8-12 hours, should have low acidity and high metal content and should be durable on aging.<sup>235</sup> The most universal and rational drier, according to Zinoviev, is lead-manganese linoleate.<sup>236</sup> Attempts have been made to set a standard for drying power of metallic

<sup>235</sup> Studies of the effects of driers on paint durability have been made by various investigators. See A. W. Van Heuwerkerth, *Am. Paint, Varnish Mfrs. Assoc., Circ.*, 1932, 407, 80; *Chem. Abs.*, 1932, 26, 2607. F. L. Chinery, *Paint, Oil, Chem. Rev.*, 1932, 94, (10), 78; *Chem. Abs.*, 1933, 27, 613. Reports of Philadelphia, California and Cincinnati-Dayton-Indianapolis Clubs, *Am. Paint, Varnish Mfrs. Assoc., Circ.*, 1933, 423, 1933, 445; *Chem. Abs.*, 1933, 27, 613, 614; 1934, 28, 348; *Brit. Chem. Abs. B*, 1933, 975, 977. J. T. Baldwin, *Am. Paint, Varnish Mfrs. Assoc., Circ.*, 1929, 356, 588; 1930, 370, 492; *Chem. Abs.*, 1930, 24, 519; 1931, 25, 220.

<sup>236</sup> Some of the many methods for producing driers include the following: Reaction of metallic oxides or salts with acids in volatile organic solvents (F. Meidert, German P. 596,878, 1934, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1934, 28, 5262. British P. 353,783, 1930; *Brit. Chem. Abs. B*, 1931, 1018).

soaps. It has been shown that one standard, the "aridyne,"<sup>227</sup> cannot be used because of the effects of concentrations, atmospheric conditions and the nature of the oils used.<sup>228</sup> The adsorption of the driers by pigments in the paint also has some effect on the drying power.<sup>230</sup>

The solubility of driers in various solvents is of considerable interest. Evans<sup>240</sup> gave some data on the solubility of soaps in transformer oil which are listed as follows:

Nickel oleate	—readily soluble	Calcium oleate	—almost insoluble
Nickel stearate	—soluble, but solution solid at ordinary temperatures	Aluminum ricinoleate	—almost insoluble
Nickel linoleate	—very slightly soluble	Tin oleate	—soluble
Nickel butyrate	—insoluble	Zinc oleate	—soluble
Lead oleate	—soluble in hot oil but not in cold	Copper oleate	—soluble

The solubility of driers in oils or diluents is said to be improved by adding a small amount of a polyhydric alcohol or of a sugar.<sup>240a</sup> In order to stabilize solutions of driers, that is, to prevent sedimentation and gelatinization, as much as 10 per cent of solid saturated fatty acids or solid free carboxylic acids or derivatives are added.<sup>241</sup> Examples are stearic, palmitic and benzoic acids, mixed crotonic and arachidic acids and mixed hippuric and salicylic acids. A phenol (e.g.,  $\beta$ -naphthol) was used by Thomas<sup>242</sup> to inhibit crystallization of driers during the drying of films of coating materials in which the driers are used.<sup>243</sup>

The behavior of aluminum soaps in various solvents is of interest because of their extensive use as flattening-agents in varnishes.<sup>244</sup> A study of the action of

reaction in the presence of amines (H. Schatz, German P. 546,771, 1930, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1932, 26, 3686; British P. 370,550, 1931, *Brit. Chem. Abs. B.*, 1932, 614; French P. 723,442, 1931; *Chem. Abs.*, 1932, 26, 4190); passing a mixture of oil and metallic oxides through a colloid mill and then heating (I. T. Osnos, Russian P. 48,948, 1929; *Chem. Abs.*, 1931, 25, 1109). Some miscellaneous driers include the soaps of wool fat (German P. 533,275, 1930, to Norddeutsche Wollkammerei and Kammgarnspinnerei; *Chem. Abs.*, 1932, 26, 610; British P. 400,797, 1933, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs. B.*, 1934, 28); soaps of fatty acids derived from coconut oil (R. A. Dunham, U. S. P. 1,982,048, Nov. 27, 1934, to Union Oil Co. of Calif.; *Chem. Abs.*, 1935, 29, 626), the soaps of hydroxy-fatty acids (British P. 346,812, 1930, to Gebrüder Borchers A.-G.; *Brit. Chem. Abs. B.*, 1931, 685; German P. 555,715, 1929; *Chem. Abs.*, 1932, 26, 6164; French P. 688,306, 1930; *Chem. Abs.*, 1931, 25, 834), the soaps of acids obtained by oxidizing mineral waxes (F. Pohl, German P. 518,094, 1927, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1931, 25, 2531; British P. 311,716, 1928; *Chem. Abs.*, 1930, 24, 979) and the heavy-metal salts of sulphonic acids from petroleum (H. E. Buc, U. S. P. 1,753,493, Nov. 12, 1929, to Standard Oil Development Co.; *Brit. Chem. Abs. B.*, 1930, 69; British P. 321,980, 1928, to Standard Oil Development Co.; *Brit. Chem. Abs. B.*, 1930, 110; S. L. Langedijk, U. S. P. 1,947,652, Feb. 20, 1934, to N. V. de Bataafsche Petroleum Maatschappij; *Brit. Chem. Abs. B.*, 1934, 1094; Dutch P. 28,002, 1932, to N. V. de Bataafsche Petroleum Maatschappij; *Chem. Abs.*, 1933, 27, 1363). A drier for Japanese lac consists of potassium dichromate, glycerol and oxalic acid (K. Usawa, Japanese P. 101,341, 1933; *Chem. Abs.*, 1934, 28, 5263).

<sup>227</sup> The drying power equivalent to 0.064 oz. oil-soluble lead per gallon of drier. (C. F. Carrier, *Am. Paint J.*, 1930, 14, (33), 70f; 14 (52D), 25; *Chem. Abs.*, 1930, 24, 3660; 1931, 25, 221.)

<sup>243</sup> Some metallic soaps have in themselves the property of preventing crystallization in varnishes. For example, lithium and cadmium resinates and oleates prevent precipitation in varnishes containing rosin (German P. 448,297, 1925, to Chem. Fabrik. K. Albert G.m.b.H.; *Chem. Abs.*, 1929, 23, 1294). Soaps of titanium, zirconium and thorium are used to prevent settling of pigments (British P. 399,183, 1932, to Titanium Pigment Co., Inc.; *Brit. Chem. Abs. B.*, 1933, 1019. French P. 734,601, 1932; *Chem. Abs.*, 1933, 27, 1215). Aluminum stearate is used similarly (E. Perry, *Paint, Varnish Prod. Mgr.*, 1931, 6 (3), 5; *Chem. Abs.*, 1932, 26, 605). Titanium stearate has been found to be better than aluminum stearate in suspending pigments. See L. W. Ryan and W. W. Flechner, *Ind. Eng. Chem.*, 1934, 26, 909. See also British P. 357,179, 1930 (*Brit. Chem. Abs. B.*, 1931, 1084) and French P. 698,153, 1930 (*Chem. Abs.*, 1931, 25, 8159) to Patent Fuels & Color Corp.

<sup>244</sup> Although aluminum soaps are preferred, other materials are used to produce a flattening effect.

these soaps has been made by Markowicz.<sup>245</sup> In aliphatic hydrocarbons pastes are formed but in aromatic hydrocarbons and terpenes the soaps swell and form gels. Licata<sup>246</sup> found that for making matt-varnishes hydrocarbons are more effective dispersing agents for aluminum stearate than are esters, alcohols and ketones. Better flat finishes are made with the stearate. Another statement of interest is that aluminum stearate is not a definite compound<sup>247</sup> and consequently its properties may be varied to suit the use intended for it.<sup>248</sup>

Metallic soaps are used to a great extent to modify paints and lacquers. They are employed in nitrocellulose lacquers to improve resistance to ultraviolet light<sup>249</sup> and to give flat finishes<sup>250</sup> or crackle finishes.<sup>251</sup> Bruson<sup>252</sup> has added the metallic salts of organic ketonic acids ( $R-CO-R'-COOH$ ) to nitrocellulose lacquers to increase their hardness and adhesiveness. A lacquer which forms washable coatings on wall-paper is made by adding a metal stearate to a nitrocellulose solution.<sup>253</sup> A varnish, stated to be elastic enough to coat natural or artificial leather is prepared by mixing nitrocellulose with oxidized cottonseed oil and 50-150 per cent of zinc naphthenate.<sup>254</sup>

Metallic resinates and other soaps find use in coating compositions for metals,<sup>255</sup> priming paints for wood or other porous surfaces,<sup>256</sup> coatings for concrete<sup>257</sup> and in non-penetrating paints.<sup>257a</sup> Some resinates are used in decorating-paints for ceramic material.<sup>258</sup>

To some extent metallic soaps are used in waterproofing-compositions for

fabrics,<sup>200</sup> paper, metals, wood, cement and concrete.<sup>200</sup> The addition of ferric linoleate to an asphaltic composition for coating rubber is said to increase the durability and luster of the final surface.<sup>201</sup> The soaps of copper, mercury and lead<sup>202</sup> are employed in toxic coating compositions and repellants for protecting materials from the action of bacteria, fungous growths and insects.<sup>203</sup> Rosenblum<sup>201</sup> used metallic soaps to modify phenol-aldehyde resins. (See Chapter 20.) As an example phenol or cresol, zinc oleate or abietate, formaldehyde (40 per cent) and colophony are heated together under reflux. The product is dehydrated and then heated with glycerol at 260°C., effecting partial esterification and yielding a resin with high melting point.

Metallic soaps have found some use in the rubber industry, acting as vulcanization accelerators,<sup>204</sup> scorch retarders<sup>205</sup> and plasticizers.<sup>206</sup> When added to rubber solutions some metallic soaps lower the viscosity so that increased amounts

of rubber can be used in paints.<sup>268</sup> To prevent uncured rubber surfaces from adhering to each other they are dusted with an aluminum or magnesium soap.<sup>269</sup> An artificial gutta-percha is obtained by adding an aluminum salt to a mixture of latex and natural resins and waxes so that the product contains more than 15 parts of aluminum soap and more than 100 parts of resin-wax mixture for each 100 parts of rubber.<sup>270</sup>

In the manufacture of lubricants extensive use has been made of metallic soaps, particularly those of aluminum and lead.<sup>271</sup> The soaps are usually mixed with petroleum stock to form oils and greases.

Mixtures of dyestuffs with metallic soaps form insoluble lake pigments whose principal use is in printing inks.<sup>272</sup>

Some of the miscellaneous uses for metallic soaps include their incorporation in electrical insulating materials,<sup>273</sup> various plastic compositions,<sup>274</sup> ceramics,<sup>275</sup>

## Chapter 38

### Natural Resin Esters

#### ESTER GUM

In the previous chapter it was noted that common rosin must be neutralized in some manner to render it useful in varnishes. An important method of accomplishing this is to convert the rosin acids into esters. The ester formed by the combination of rosin with 10-15 per cent of glycerol is known commercially as ester gum and is used extensively in varnish manufacture. Ester gum has decided advantages over both raw and hardened rosin with regard to durability, moisture-resistance and freedom from livering with basic pigments.

Although glycerol is the most commonly used esterification agent other polyhydric alcohols and to some extent monohydric alcohols and phenols are used. The agent employed must be cheap enough for commercial use and at the same time must impart good color and hardness to the ester. In varnish and lacquer manufacture the requirements for ester gum are pale color, softening point of 82-86°C. and acid number of about 5-10. To obtain a good grade of ester gum the rosin used must be clear and must have a high melting point and high acid number.<sup>1</sup>

In the formation of ester gum from glycerol and rosin complete esterification should yield glyceryl triabietate, and experience has shown that this ester has the most desirable properties. In actual practice, however, complete esterification is difficult so that the ester gum obtained consists of glyceryl triabietate plus small amounts of the mono- and diabietates and, in addition, some decomposition products and the original unsaponifiable matter in the rosin. Considerable technique is required to obtain an ester gum of satisfactory quality.

Assuming that rosin consists entirely of abietic acid,  $C_{19}H_{30}COOH$ , the amount of glycerol required to form the triabietate would be slightly more than 10 per cent of the weight of rosin.<sup>2</sup> In practice, in order to ensure complete esterification 12-15 per cent of glycerol is employed. When excess glycerol is used it can be removed from the ester gum by vacuum distillation. The presence of free glycerol in the product lowers the moisture-resistance of varnishes in which the ester gum is used.<sup>3</sup>

The formation of rosin esters was first accomplished by Schaal.<sup>4</sup> Natural resin acids are heated with hydroxy compounds (monohydric and polyhydric alcohols)

<sup>1</sup> See S. Babcock, *Proc. Am. Soc. Testing Materials*, 1930, 30 (2), 795; *Chem. Abs.*, 1931, 25, 2310.

<sup>2</sup> The structure of abietic acid is given in Chapter 37.

<sup>3</sup> General reviews on the preparation of ester gums are given in the following articles: H. Brendel, *Farben-Ztg.*, 1925, 31, 578; *Chem. Abs.*, 1926, 20, 832. B. hols, phenols and carbohydrates) to form the esters.<sup>5</sup> Acids or acid salts capable of absorbing water are sometimes added. An essential feature is the removal of the water formed by esterification. If the process is carried out under pressure the water collects in the form of steam, and if the esterification is performed in a partial vacuum this suffices for the removal of water. A third method of water removal is to pass heated neutral gases through the reaction mixture.

In one example of ester formation rosin is heated to 350°C. *in vacuo* to remove volatile constituents. The hard residue is mixed with 10 per cent of its weight of anhydrous glycerol and heated at 250°C. under several atmospheres pressure. Steam which forms in the reaction is allowed to escape. When the esterification is complete the esters are vacuum distilled to separate soft and hard portions.

In the partial-vacuum method, rosin is heated in a retort to 180-210°C. and 10-11 per cent of its weight of glycerol is added in a thin stream with constant stirring.<sup>6</sup> A vacuum of about 100 mm. is maintained. When all the glycerol has been added the temperature is gradually raised to 280°C. and agitation is continued until esterification is complete.<sup>7</sup> The crude ester is made harder by removing volatile constituents either by vacuum distillation or by distillation in a stream of an indifferent gas.<sup>8</sup>

Experiments were conducted by Murray<sup>9</sup> to determine the best conditions of temperature and time for the formation of ester gum. When glycerol was added to molten rosin at 150°C. reaction began immediately, accompanied by foaming of the mixture due to the formation of water. Although the fused material was clear, drops removed and cooled showed a milky appearance. The acid number decreased rapidly, but continued heating at 150-250°C. for hours failed to neutralize a great portion of the rosin, irrespective of the amount of glycerol used. When the temperature was raised to 290°C. (the boiling point of glycerol), however, the esterification was completed rapidly, forming an almost neutral product possessing an acid number of less than 5 when carefully prepared.<sup>10</sup> Murray found it necessary to keep the mixture covered during the reaction in order to prevent excessive discoloration and to reduce loss of glycerol which is rapidly carried off by the water vapor. He did not recommend the use of a condenser since water vapor must be allowed to escape.<sup>11</sup> The ester obtained by Murray possessed a lower melting point than the original rosin and was slightly more tacky. The author has observed, however, that a well-esterified product, if entirely free from uncombined glycerol, is less tacky than raw rosin.

In further experiments Murray found that esterification of rosin with glycerol is completed in 15 minutes at 290°C. Using 12 parts of glycerol with 100 parts of rosin an ester with an acid number of 5-10 was obtained in that time. It was noted however that continued heating caused a gradual increase in acidity, attributed to the decomposition of the ester. This behavior is analogous to that of the glyceryl esters of fatty acids (e.g., linseed oil), which on prolonged heating

<sup>5</sup> An alternative method suggested by Schaal consists in heating metallic salts of the resin acids with halogen or sulphur compounds of phenols.

<sup>6</sup> The apparatus used by Schaal is shown in Figure 121.

<sup>7</sup> This is determined by the soda test. Esterification is complete if a test portion dissolved in benzene or ether does not give up any soluble portions when mixed with an aqueous solution of sodium carbonate.

<sup>8</sup> Similar methods are outlined by M. Bottler in "Harze und Harzindustrie," Verlagsbuchhandlung Dr. M. Jänecke, Hannover, 1907.

<sup>9</sup> A. Murray, *Chem. Met. Eng.*, 1921, 25, 475.

<sup>10</sup> The fact that the temperature must be raised to complete the esterification is attributed by W. F. Darke and E. Lewis (*J.S.C.I.*, 1928, 47, 1086) to a final condensation action.

<sup>11</sup> Nevertheless, the author has obtained good results with an air condenser of such length that the steam will escape but the glycerol for the most part will return to the reaction vessel.

yield free fatty acids. It is necessary, therefore, to determine when esterification is complete and discontinue heating at that time.

Ellis and Rabinovitz<sup>12</sup> investigated the effect of conditions on the formation of rosin esters. Partial esterification was brought about by bubbling various gases through a molten mixture of rosin and glycerol at 280-300°C. The gases used were hydrogen chloride, carbon dioxide, hydrogen, air and oxygen. A product having an acid value of about 7 per cent of the original value of the rosin was obtained by bubbling hydrogen chloride for two hours through a mixture of 50 parts of rosin and 5-8 parts of glycerol at 285°C. The resulting ester was of good color and contained no hydrochloric acid. A reduction in acidity of over 80 per cent resulted from passing carbon dioxide for 75 minutes through a rosin-glycerol mixture at 290°C. With the exception of hydrogen chloride, the action of the gases is largely mechanical, serving to bring the reactants into intimate contact and to remove water vapor. Non-oxidizing gases proved more satisfactory than hydrogen chloride or air since the air caused darkening and the hydrogen chloride showed a tendency to form a soft product.

The method of esterification was improved by using a stirring device so that the mechanical effect of the gases was obtained without the disadvantage of loss of glycerol. Another improvement was the use of a reflux condenser arranged to permit the escape of water vapor but to condense glycerol vapors and return them to the reaction vessel. Products obtained in this way had in some cases acid numbers as low as 6 or 7. A closed kettle equipped with a stirrer is best for the production of ester gum of good quality.

Improvements in the manufacture of ester gum have involved the use of various catalysts. Ellis and Weber<sup>13</sup> proposed to utilize basic substances capable of forming resinates. The resinates then react with glycerol to form a resinous complex. In one example 300 parts of rosin and 12 parts of quicklime are heated at 290°C. for 30 minutes. Then 40 parts of glycerol are stirred in and the mixture is agitated at 270-290°C. for another 30 minutes. The resulting product has an acid number of 9. Materials proposed in place of quicklime include calcium cyanamide, magnesia and barium oxide. In using this method Lafon<sup>14</sup> noticed that calcium resinate has a decided catalytic effect.<sup>15</sup> Kulas and Scheiber<sup>16</sup> obtained a non-sticky ester by mixing 3 parts of slaked lime with 100 parts of rosin and 5 parts of glycerol and working the mass on rolls heated to 250°C.

Sterling, Grothsch and Veitch<sup>17</sup> found that zinc and its salts are effective catalysts in preparing resin esters. When zinc metal is employed it is either introduced into the reaction mixture as a powder or the reaction container is lined with zinc. The catalyst speeds the reaction to four times its normal rate and only about 0.2 per cent of the zinc is taken up by the rosin. In one example 300 parts of rosin, 40 parts of glycerol and 1 part of finely divided zinc are heated together for 30 minutes at 275-280°C., using an air-cooled reflux condenser. The condenser is then removed and the temperature is raised to 310°C. to re-

move excess glycerol. The product is said to have an acid number less than 1.5 and similar results are obtained using zinc oxide or zinc carbonate.<sup>18</sup>

Investigations made by Beegle<sup>19</sup> showed that steel is an efficient catalyst for rosin-ester formation but that this metal has the disadvantage of giving a dark-colored product. Other catalysts tested were aluminum, copper, lead acetate and cobalt sulphate. An aluminum vessel was recommended for the esterification since it yields a clearer and paler product and has a greater catalytic effect than copper.<sup>20</sup> Kogan<sup>21</sup> found that in the preparation of glycerol esters of rosin by heating the components in a current of air at 275-280°C. the best catalyst is zinc. Sodium acetate, magnesium, aluminum and cadmium follow in decreasing effectiveness. Although zinc chloride, hydrogen chloride and ferric chloride are very efficient catalysts for the reaction they cause a certain amount of decomposition, yielding products which are half liquid and very sticky.

According to Voss<sup>22</sup> the formation of resin esters is greatly accelerated by the addition of a small amount of an oxygenated phosphorus compound (e.g., orthophosphoric or orthophosphorous acid). Other catalysts used by Voss in resin-ester formation are aliphatic hydroxy-carboxylic acids of low molecular weight.<sup>23</sup> In one example 300 parts of rosin are heated to 180°C. with 35 parts of glycerol and then 25 parts of diglycolic acid are introduced. The mixture is held at 280-285°C. for 1 hour in an atmosphere of carbon dioxide and for an additional 30 minutes in a vacuum at the same temperature. The product is said to be a pale, ash-free resin with an acid value of 22.

Drying oils, particularly tung oil, have a catalytic effect on esterification of rosin. This is dealt with later in the chapter.

Williamson and Beisler<sup>24</sup> suggested a process for making ester gum directly from crude turpentine. The mixture is strained and heated with 12.5 per cent of glycerol to 170°C. to drive off the water and part of the turpentine. The still is equipped with a reflux condenser adjusted to allow the escape of the water and turpentine but to retain the glycerol. A slow current of steam is passed through the mass until a temperature of 240°C. is reached. Then the steam is shut off and the temperature is increased to 290°C. where it is maintained for 1.5 hours to insure complete esterification of the rosin. Next, the reflux condenser is removed and for 10 to 15 minutes a rapid flow of steam is passed through the mixture, maintained at 275-290°C. to remove any excess of glycerol. This procedure is said to give light-colored products.

**Use of Other Polyhydric Alcohols.** If glycerol is heated with certain dehydrating agents, glycerol ethers or polyglycerols are formed. Thus two molecules of glycerol can condense to form diglycerol, one molecule of water being removed.<sup>25</sup>

<sup>25</sup> The condensation of glycerol to polyglycerol is catalyzed by a small proportion of iodine according to H. Hibbert (*J.A.C.S.*, 1915, 37, 1748. U. S. P. 1,126,407, Jan. 26, 1915; *Chem. Abs.*, 1915, 9, 694). For preparation of polyglycerols see R. Leopold and K. Billig, German P. 566,032, 1931, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1933, 27, 998. See also Chapter 42.

The use of polyglycerols to form rosin esters was advocated by Symmes<sup>20</sup> who found that such esters are harder and have a higher melting point than the usual ester gum. For the formation of polyglycerols Symmes used anhydrous sodium acetate or sodium hydroxide as a polymerization catalyst. As an illustration of the method employed, 200 parts of glycerol, 5 parts of zinc dust and 1 part of anhydrous sodium acetate are heated under reflux at 270-290°C. for 2 hours. Then 1000 parts of rosin are added and the mixture is heated at 290°C. for 15 hours. Unreacted constituents are removed by heating under reduced pressure. The resulting diglycerol ester has an acid number of 12. The method may be varied by separating the diglycerol from the other polyglycerols after the first step, and then reacting the diglycerol with rosin or pure abietic acid.

It has been stated that in addition to the harder product obtained by the use of polyglycerol there is also the advantage that the presence of an excess of polyglycerol in the ester has no harmful effect in lacquers whereas free glycerol in lacquers and varnishes lowers their moisture-resistance. Indeed some polyglycerols are reported to assist in the blending of ester gum with nitrocellulose.<sup>21</sup>

Similar to the use of glycerol is the employment of glycols to esterify rosin. Norman<sup>22</sup> obtained rosin esters of ethylene glycol and of diethylene glycol with the use of catalysts such as zinc dust or boric acid.<sup>23</sup> In one case 60 parts of diethylene glycol, 300 parts of rosin and 5 parts of catalyst are heated at atmospheric pressure for 5 hours at 250-260°C. under reflux and for 10 hours more without a condenser. Unreacted constituents are then removed by heating at 300°C. at about 15 mm. pressure. The result is 270 parts of ester with an acid number of 22 and a melting point of 60°C.

Esters of rosin with mono-esters and ethers of the glycols have also been prepared.<sup>20</sup> In one example 300 parts of rosin are heated with 152 parts of diethylene glycol monobutyl ether at 200-220°C. in an atmosphere of carbon dioxide. After 30-70 hours' heating the excess reagent is removed by blowing with carbon dioxide at 250°C. The product (yield 408 parts) has an acid number of 20-21.

In a similar manner polyhydric alcohols with more than 3 hydroxyl groups can be used to form rosin esters. Schmidt and Seydel<sup>24</sup> used sorbitol; and Bent and Johnston<sup>25</sup> employed pentaerythritol,  $C(CH_2OH)_4$ , erythritol,  $C_4H_8(OH)_4$ , and enneaheptitol,  $C_6H_{14}(OH)_7$ . Schaal<sup>26</sup> proposed the use of mannitol as well as carbohydrates. In experiments conducted by the author attempts to esterify rosin with carbohydrates yielded under ordinary conditions no satisfactory products. The rosin remained practically unchanged and the carbohydrates were converted into carbonaceous masses.<sup>21</sup>

The use of various halogen derivatives of polyhydric alcohols and ethers to

<sup>27</sup> E. Schaal, *loc. cit.*

<sup>28</sup> According to F. R. Suter (U. S. P. 905,384, Dec. 1, 1908, to New Process Varnish Co.; *Chem. Abs.*, 1909, 3, 959) dehydrated molasses will combine with rosin. The molasses is added to melted rosin and the product is mixed with an asphalt-distillate (primol) diluted with turpentine or alcohol to form a varnish.

produce resin esters has been proposed. For instance, Johnston<sup>37</sup> obtained glyceryl diabetate by the action of glycerol dichlorohydrin on sodium resinate. In the method used 75 parts of rosin are dissolved in a solution of 10 parts of sodium hydroxide in 100 parts of alcohol and the solution is refluxed at 80°C. Then 25 parts of glycerol dichlorohydrin are added gradually and the refluxing is continued for about 15 hours. The glyceryl diabetate formed is freed of sodium chloride by filtration, and of unreacted constituents by distillation. Other esters are formed similarly by using various chlorohydrins and bromohydrins, e.g., ethylene chlorohydrin or bromohydrin, propylene chlorohydrin and glycerol monobromohydrin.<sup>38</sup>

Langmeier<sup>37</sup> obtained glycol esters of abietic acid by the action of olefin dihalides on sodium resinate under pressures of 1-20 atmospheres and at temperatures of 75-200°C. In one case 45 parts of rosin are dissolved in 65 parts of an alcoholic solution containing 6 parts of sodium hydroxide. To this are added 10 parts of ethylene dichloride and the mixture is heated at 135-140°C. for 2 hours under 6-7 atmospheres pressure. The resulting ester has an acid number of 34.

Various aliphatic chloroethers were used by Humphrey<sup>38</sup> to form rosin esters. As an illustration a solution of 60 parts of sodium hydroxide and 500 parts of rosin in 700 parts of alcohol are heated with 110 parts of  $\beta,\beta'$ -dichloroethyl ether for 8 hours at 160°C. under a pressure of 15 atmospheres. Unreacted material is removed by distillation, leaving about 430 parts of diglycol diabetate. The product is softer than rosin and has an acid number of 5.

The esterification of colophony with alkylene oxides yields hydroxyalkyl esters of abietic acid, according to Schmidt and Meyer.<sup>39</sup> In one example, rosin is heated under pressure with ethylene oxide at 160-170°C. yielding a balsam-like resin. Similar treatment of ester gum was suggested. The resins are hardened in a vacuum or they may be acylated in the presence of a condensing agent, e.g., boric acid. The products can be used as softening agents with nitrocellulose lacquers.

**Esterification with Monohydric Alcohols.** The esters of rosin with aliphatic monohydric alcohols are for the most part viscous liquids some of which find use in lacquers particularly those made with nitrocellulose.<sup>40</sup>

A number of abietates of monohydric alcohols and phenols have been prepared and described by Kesler, Lowy and Faragher.<sup>41</sup> The alkyl esters were prepared by reaction of sodium abietate and the appropriate alkyl p-toluenesulphonate. The esters of the phenols were obtained by the action of phosgene on mixtures of dry sodium phenolates with sodium abietate. Special methods were used to form benzyl, cholesteryl and cetyl abietates. Some of the properties of the esters are recorded in Table 37.

In one of the various methods employed by Johnston<sup>42</sup> to produce alkyl

esters of rosin an alkyl sulphate or halide is caused to react with rosin in alkaline solution. Alkyl sulphates are preferred to alkyl halides. As an example of the method used, 20 parts of sodium hydroxide are dissolved in 25 parts of water and 150 parts of ethyl alcohol. After the addition of 150 parts of rosin the mixture is heated under reflux until a clear solution results. Then 40 parts of diethyl sulphate are introduced into the solution and the alcohol is distilled off. The mixture remaining is heated and stirred for 1-2 hours at 145°C. The product, ethyl abietate, is removed by vacuum distillation and is obtained (in 80-85 per cent yield) as a clear ester with an acid number of about 10. An advantage of the method, according to Johnston, is that impure and dark-colored rosins can be employed because in the final distillation the color bodies do not distil over with the ester.

Johnston prepared alkyl rosin esters also by direct reaction between rosin and aliphatic alcohols. In one method a sulphonic acid is used as catalyst.<sup>43</sup> For example, to form ethyl abietate, 320 parts of rosin, 500 parts of ethyl alcohol and 10 parts of p-toluenesulphonic acid are heated for 4 hours at 160°C. under 11-12 atmospheres pressure. Excess alcohol is removed, the catalyst is neutralized with soda ash and the ethyl abietate (73 per cent yield) is obtained by distillation. Similar methods are employed for amyl and butyl abietates. By using higher temperatures (260-360°C.) and higher pressures (400-1700 pounds) and employing anhydrous alcohols esterification is effected without a catalyst.<sup>44</sup> Ethyl abietate was made by Gubelmann and Henke<sup>45</sup> by using as condensing agent either hydrochloric acid, sulphuric acid or oleum. For instance a mixture of 240 parts of 95 per cent ethyl alcohol, 80 parts of abietic acid and 36 parts of oleum (25 per cent) is refluxed until the abietic acid is 90 per cent esterified. The mass is diluted with water and the excess alcohol distilled off. Distinct layers of ethyl abietate and of sulphuric acid are found on standing. These are separated and the ethyl abietate is recovered by fractional vacuum distillation.

In a method devised by Butts,<sup>46</sup> ethyl abietate is produced by heating an ethyl

alcohol solution of abietic acid in a reaction chamber at 265°C. under a pressure of 800 pounds per square inch.

The reactions of high-molecular-weight alcohols with abietic acid have been studied in attempts to prepare resins with special properties. Stearyl alcohol and colophony were heated at 200°C. for a prolonged time by Fritz.<sup>47</sup> A liquid is obtained but upon standing it changes suddenly to a golden fatty mass having properties similar to those of rosin. A varnish resin can be made from ceryl, myricyl or other alcohols of the wax series and mineral or organic resins.<sup>48</sup>

Fonrobert and Greth<sup>49</sup> proposed changing abietic acid to abietic anhydride by treating colophony with acetic anhydride, and then esterifying with alcohols to give esters.

In the preparation of rosin esters, the chloride derivatives of monohydric alcohols are sometimes substituted for the alcohols. Previous mention has been made of a similar substitution in the case of polyhydric alcohols. The chloride derivatives often react more quickly with abietic acid than do the alcohols. Kränzlein and Voss<sup>50</sup> obtained a varnish resin by using 160 parts of rosin, 40 parts of benzyl chloride and 0.4 part of zinc chloride. The temperature was held at 100°C. until hydrogen chloride ceased to evolve and then maintained at 200°C. for one hour.

The catalysts suggested for esterifications with the organic chlorides are aluminum chloride, ferrous sulphate, cupric chloride, zinc resinate, tin, zinc and iron. Rosin has been used with the following organic chlorides; those of benzyl, benzal, tolyl, xylyl, methylbenzyl, dimethylbenzyl and isopropylbenzyl. All the esters prepared from these compounds were oil-soluble. To make them water-soluble, they are sulphonated.<sup>51</sup>

Another method of esterification calls for refluxing the sodium salt of abietic acid with an organic chloride. For instance, Crane<sup>52</sup> refluxed sodium abietate with benzyl chloride for 4 hours. The resulting ester was somewhat softer than rosin. Voss<sup>53</sup> used a solution consisting of alkali, rosin and ethyl chloride or chlorohydrin to prepare an oil-soluble resin.

A resin ester was made by Mossgraber<sup>54</sup> from sodium resinate and acetyl chloride. The product when mixed with  $\alpha$ -naphthylamine gave a resin for insulating-varnishes.

**Esterification of Rosin with Phenols and Naphthols.** The success that accompanied the esterification of rosin with alcohols led to investigations using other organic hydroxyl compounds. Among those first tried were phenol and naphthol.<sup>55</sup> The reactions between phenols or naphthols and rosin do not proceed as smoothly as those with glycerol.<sup>56</sup> The properties of the resins obtained from phenols and naphthols are such that the more easily prepared ester gum can frequently be used instead. In an attempt to get a more precise procedure

<sup>56</sup> In the author's laboratory, phenol, cresol, ethyl alcohol, aniline, and naphthylamine esterified by usual procedures did not give products approaching neutrality. Benzyl alcohol was the best compound tried.

for the esterification of rosin with phenol, Kogan, Makarenko and Sikar<sup>57</sup> made a study of conditions affecting these reactions. Phenol and rosin mixed in widely different proportions did not react when heated to 175°C. Partial esterification resulted from a 4-hour heating at 280°C. under 10 atmospheres pressure. Under these conditions a catalyst was necessary to complete the reaction. Zinc chloride, calcium oxide, sodium chloride, lead, iron, magnesium, and zinc were found effective. The phenol-rosin ester finally obtained was a soft sticky mass that would harden somewhat at 200°C. A varnish made from the hardened product was slow-drying and was inferior to ester gum in durability.

Some of the difficulties encountered in the esterification of rosin with phenol or cresol can be overcome by the use of proper catalysts. With boron trifluoride, a clear resin is produced and a lower temperature can be used. If the rosin and cresol are dissolved in carbon tetrachloride, the esterification occurs at room temperature.<sup>58</sup> Boric acid, which is also a catalyst for the manufacture of ester gum, has been suggested for the reaction between cyclohexanol and abietic acid. The cyclohexyl ester is a plasticizer for cellulose lacquers.<sup>59</sup> Aqueous mineral acids aid the combination of phenols with rosin. Resins made with help of these catalysts have melting points near 100°C.<sup>60</sup> A proposal by Pyhälä<sup>61</sup> calls for the preparation of rosin esters by the reaction of rosin with the calcium salts of the phenols at 180-220°C. The experimenter made esters of phenol, cresol, borneol,  $\beta$ -naphthol, resorcinol and glycerol from their calcium compounds. All the resins produced had a clear color. The low temperatures used probably help to bring about this result.<sup>62</sup>

Another variation in the procedure for esterifying rosin with phenols is to employ abietic anhydride in place of rosin.<sup>63</sup> Abietic acid is converted into abietic anhydride by treatment with acetic acid anhydride.<sup>63a</sup>

Resins to be employed in varnishes, lacquers and paints have been made by heating a mixture of tetrahydronaphthol and abietic acid.<sup>64</sup> Varnish resins were obtained by Binapff<sup>65</sup> by esterifying rosin incompletely with phenol and then completing the reaction with butyl or benzyl alcohol.

A water-soluble ester is prepared by condensing colophony with 1-naphthol-5-sulphonic acid.<sup>66</sup>

**Esterification of Rosin with Esters.** A variation in the preparation of rosin esters calls for heating abietic acid with a high-boiling ester to bring about an interchange of groups between the acid and ester. If the ester chosen has a high boiling point the required temperature can be maintained without pressure. The production of a neutral ester is facilitated if the resulting acid is volatile at

the temperature of the reaction. Hesse,<sup>67</sup> in employing this method heated dimethyl and diethyl phthalate with colophony. In more recent work rosin has been heated with dibutyl phthalate, benzyl acetate, stearin and acetamide to give the corresponding butyl, benzyl, and glyceryl abietate and abietamide. To make butyl abietate, dibutyl phthalate and rosin (equal parts) were heated at 295-300°C for 8 hours. After the excess of abietic acid had been removed by benzene the butyl abietate had an acid number of 2.7.<sup>68</sup>

Aluminum has been employed as a catalyst in preparing esters by heating monoacetin, diacetin, glycol monoacetate or propylene glycol monoacetate with abietic acid.<sup>69</sup>

**Esterification of Rosin in the Presence of Drying Oils.** One of the advances in ester-gum manufacture was the addition of tung oil during the process of esterification. Tung oil acts as a catalyst for the reactions of glycerol with rosin. The resins produced are clear and make varnishes of good durability. The esters made have acid numbers of 7-21 and therefore may be used with basic pigments. The fume-loss during manufacture is less if tung oil is present. Gardner and Coleman<sup>70</sup> studied the esterification of rosin in the presence of tung oil in an open kettle. Tung oil up to 25 per cent of the rosin used improved the quality of the final resin. The addition of lime soap, (e.g., calcium resinate or tungate) accelerates the reactions of rosin and glycerol under these conditions. The temperature was maintained at 260°C during the process.

An illustration of the making of varnish utilizing these principles is given as follows:

*Waterproof Spar Varnish*

Rosin . . . . .	100 parts
Glycerol . . . . .	20 parts
Lime . . . . .	6 parts
Tung oil . . . . .	240 parts
Manganese tungate paste drier . . . . .	14 parts
Lead tungate paste drier . . . . .	8 parts
Turpentine . . . . .	66 parts
Mineral spirits . . . . .	300 parts

The method of incorporation is to melt the rosin with 25 parts of tung oil at 175°C. The lime is then added and thoroughly stirred into the mixture. At the same time the temperature is raised to 260°C. to dissolve the lime and bring about a partial polymerization of the tung oil. When the glycerol is added the temperature is lowered to 175°C. and then raised to 260°C. and held at that point for an hour. The mass is allowed to cool slightly when the remaining tung oil is added. Caution must be exercised in adding the oil to avoid a drop in temperature below 230°C. as the ester may be thrown out of solution and is redissolved with difficulty. The driers are added and the melt maintained at 230°C. to body the oil. This step may require from 30-60 minutes. A sample (pill) should be stiff but not gelatinous or stringy. When the requisite body is obtained the batch is cooled and thinners (turpentine first) added at 177-204°C. If the body of the varnish is heavy a larger proportion of thinners can be added. The turpentine may be replaced, at least to a very large extent, by mineral spirits. This varnish dried hard in 5 hours to give a flexible coating. A panel varnished with the composition showed no whitening or softening of the film after exposure to boiling water for 15 minutes. The acid value of the varnish was 5-6.<sup>71</sup>

<sup>70</sup> H. A. Gardner and R. E. Coleman, *Crc., Paint Mfrs. Assoc.*, 1920, *Spec* 101; *Chem. Abs.*, 1920, 14, 2992. These workers gave the name "Tunga Resin" to their product.

<sup>71</sup> The circular by Gardner and Coleman contains directions for making both a short and a long oil varnish by this method. A short oil varnish is one containing 12 gallons or less of oil to 100 pounds of resin; one with 20 gallons or more is called a long oil varnish.

The esterification of rosin with glycerol in the presence of tung oil was further studied by Beegle.<sup>72</sup> He confirmed the fact that tung oil is an excellent catalyst for the formation of ester gums. Other substances that were found to be good catalysts include iron, cobalt, copper and aluminum. His results indicate that the use of tung oil in conjunction with an aluminum kettle would shorten the process by 30 minutes.<sup>73</sup>

Beegle concluded from his investigations that about 11 per cent of tung oil (based on rosin used) gave the clearest resins. The amount suggested was 1.5 gallons of tung oil to 100 pounds of rosin. Beegle also explored the possibility of esterifying rosin in the presence of a large proportion of tung oil to obtain a product that only needed thinning with turpentine when cooled. A mixture of 1160 grams of rosin, 160 grams of glycerol and 2268 grams of tung oil was heated to 270°C. The course of reaction was followed by determining acid numbers every 15 minutes. The acidity did not decrease as rapidly as expected, the indications being that too much oil was used.

The esterification of rosin in a congealed tung-oil-rosin varnish was proposed by Steinhoff<sup>74</sup> as a means of reclaiming the varnish. After the glycerol reacts with the rosin the varnish may be thinned as usual.

The esterification of rosin in the presence of acids derived from drying oils has been suggested as a means for the production of certain synthetic resins. Linoleic acid was used by Rosenblum.<sup>75</sup> His method proceeds as follows: 280 pounds of linoleic acid are heated to 250°C. with 100 pounds of glycerol until the acid disappears and thereupon 604 pounds of abietic acid are added. The mass is heated to 250°C. After cooling, an oil-soluble fusible resin is obtained. Linoleic acid was used with polyalcohols and colophony by Krzikalla and Wolff.<sup>76</sup> In these reactions a reduced pressure and moist atmosphere improve the quality of the final product.

Scheiber<sup>77</sup> substituted ricinoleic acid for linoleic. A mixture of ricinoleic acid and glycerol was heated and then rosin was added to neutralize excess glycerol. To aid the reaction between rosin and glycerol the whole was heated again. Oleic or polybasic organic acids can be mixed with resin acids before or after esterification with glycerol.<sup>78</sup>

Synthetic drying oils are said to be obtained by condensing castor oil with glycerol and esterifying the resultant product with a resin acid.<sup>79</sup>

**Reactions of Rosin with Drying Oils.** The reactions of rosin with drying oils have been investigated from two viewpoints; first, to determine if fatty oil glycerides of the oil react with rosin during the cooking of varnishes, and second, to find new methods by which resins and lacquers may be produced. A study was made by Pistor<sup>80</sup> to determine whether abietic acid and refined linseed oil or tristearin combine during the preparation of oil varnishes. In the experiment, abietic acid was mixed with the oil and after heating, the unesterified acid was removed by vacuum distillation. The proportion of acid left was found to depend upon time and temperature. The results obtained indicated only slight inter-

esterification between drying oils and rosin during the cooking of oil-rosin varnishes.

From experiments with rosin and linseed oil, Ragg<sup>81</sup> concluded that no glycerol-rosin ester is formed at the expense of the fatty acid glyceride. Upon heating rosin and linseed oil at 300°C. it was found that the free-fatty-acid content remains the same as that existing in the original fatty oil. Scheiber<sup>82</sup> believes that in the cases of rosin, Congo and Manila there is some displacement of the fatty acids of glycerides by resin acids during the cooking of varnishes. Wolff<sup>83</sup> thought that the heating of metallic resinates with linseed oil resulted in the formation of resin glycerides and metallic linoleates.

The reaction between rosin and oils has been suggested as a means of producing new resins. Bruson and Robinson<sup>84</sup> obtained a fusible product as a still-residue in the vacuum distillation of a mixture of castor oil and rosin. Bürstenbinder<sup>85</sup> utilized the action of tung oil with rosin to reliquefy coagulated tung oil.

Acids derived from drying and semi-drying oils may replace oils in the reactions with resin acids. The acids derived from tung, rapeseed and castor oil were condensed with rosin to produce lacquer substitutes.<sup>86</sup> Materials of a related nature proposed by Breyer<sup>87</sup> were made from hydroxyalkyl esters of drying oil acids and resin acids. A synthetic shellac was prepared by condensing the hydroxy acids from castor oil with oxidized rosin.<sup>88</sup>

Krzikalla and Wolff<sup>89</sup> used ricinoleic acid in conjunction with resinic acids. For example; 15 parts of ricinoleic acid were mixed with 13.5 parts of colophony and the mixture kept at 250°C. under reduced pressure for 10 hours, yielding a brown viscous oil, soluble in most organic solvents. Other substances that have been condensed with rosin include dihydroxyabietic acid, dihydroxystearic acid, salicylic acid, naphthenic acids, mesityl oxide and phorone.<sup>90</sup> Acids and alkalis are catalysts for the reactions of drying oil acids with resinic acids. If an inert atmosphere is used the resins produced are of better quality.<sup>91</sup>

**Chlorination of Rosin.** Chlorinated rosin is of interest because of its compatibility with cellulose acetate. Lacquers containing this resin give films of good flexibility and gloss. The addition of chlorine raises the softening point of rosin. The final resins are soluble in alcohol and benzene.

Rosenthal<sup>92</sup> chlorinated rosin by dissolving it in 10 times its weight of 19.5 per cent caustic soda solution and treating with a stream of chlorine gas. The precipitated resin was filtered and washed. The final product contained 5.5 per cent chlorine and had an acid number of 131.

Chlorine can be added to rosin under other conditions. Povlovski and Dmitrov<sup>93</sup> chlorinated rosin in the powdered form by heating it in an atmosphere of

chlorine. Lister<sup>94</sup> maintained melted rosin at 150-350°C. while treating with a halogen. Hypochlorous acid as well as chlorine will react with rosin.<sup>95</sup>

A chlorinated rosin containing 24.9 per cent chlorine and possessing a melting point of 100°C. was prepared by Dykstra.<sup>96</sup> He suggested that it be used as a soldering flux. Dux<sup>97</sup> obtained a shellac substitute by reacting chloroabietic acid with trihydroxystearic acid.

**Miscellaneous Reactions of Rosin.** From the foregoing it will be observed that the reagents proposed for combination with rosin are numerous and varied. Many of the products are of resinous nature but some of them differ so widely from the original rosin that they can hardly be called true resins.

Rosin treated with volatile inorganic halides gives resins having higher softening points, higher molecular weights and lower iodine numbers than the original substance. These resins are of interest because they are compatible with nitrocellulose. The halogenated product may be esterified with glycerol and alcohols by methods similar to those used for rosin. The resins are made by dissolving rosin in carbon tetrachloride, adding boron trifluoride and passing nitrogen through the solution. The reaction takes 33-35 hours at 10-11°C. Batavian dammar, gum mastic, copal and resin esters may replace rosin. The inorganic halides proposed in addition to boron trifluoride were the chlorides of titanium, aluminum and tin.<sup>98</sup>

Nitriles of abietic acid are made by treating abietic acid with gaseous ammonia. The nitriles are viscous balsams which are purified by distilling under reduced pressure. Dehydrating agents (e.g., aluminum oxide, thorium oxide, silica gel), are catalysts for the ammonia-rosin reaction. One method of preparation is given as follows: Gaseous ammonia and a benzene solution of rosin are heated to 350-360°C. in the presence of silica gel. The nitrile is separated from the benzene by distillation.<sup>99</sup>

The reaction of maleic anhydride or aconitic acid with rosin at 110°C. yields a resinous product with an iodine number of 63 (as compared with 180 for rosin) and a softening point of 100°C.<sup>100</sup> Acetylene was passed into rosin in the presence of mercuric acetate by Balle.<sup>101</sup> The resulting resin was soluble in lacquer solvents and fatty oils and possessed good drying qualities.

Some amine types of compounds have been suggested as reactants with rosin. A product made from trihydroxyethylamine and rosin is said to have good resistance to alkalis.<sup>102</sup> An example of the proportions used follows: A mixture of 37 parts of trihydroxyethylamine and 213 parts of rosin is heated in such a manner that a temperature of 300°C. is reached in 2-4 hours. The product melts at 75°C. and is soluble in benzol, ethyl acetate and drying oils.

Glycerylamine neutralized with abietic acid yields a hard resin that is soluble

in benzene and can be added to lacquers.<sup>101</sup> Aromatic amines, e.g., aniline, react with colophony to give a product that may be condensed with furfural.<sup>101</sup>

Binapfl<sup>102</sup> raised the softening point of rosin by treatment with a carbazole. For instance rosin and diisopropylcarbazole were dissolved in benzene and held at 18°C. in the presence of boron trifluoride to give a product softening at 126°C.

Among other compounds, organic sulphonic acids have been proposed as alkylating agents for abietic acid. Voss<sup>103</sup> suggested that colophony, after treatment with sodium hydroxide, be alkylated with methyl-p-toluenesulphonate. After the removal of sodium p-toluenesulphonate by washing, the residue yielded a yellow viscous mass that behaved like Venice turpentine. Vulcanizable resins were produced by Auer<sup>104</sup> from colophony and  $\beta$ -naphthol-3,6,8-trisulphonic acid, dichlorobenzenesulphonic acid, sulphasalicylic acid or p-toluenesulphonyl chloride. The mixtures were heated for several hours at 300°C. under a vacuum to obtain the resin. Products with entirely different properties were prepared by heating abietic acid with sodium 3-chloro-2-hydroxypropanesulphonate or sodium bromoethanesulphonate. The temperature was held at 110-140°C. for 4-15 hours. Water containing small percentages of these reaction products may be used for cleaning textile fibers.<sup>105</sup>

Rosin was utilized by Pungs<sup>106</sup> to modify the properties of lignite wax. A mixture of 50 parts of wax and 20 parts of rosin was heated with air bubbling through for 3 hours at 160-170°C. The final wax melted at 80°C. and had an acid number of 42. A modification of this procedure calls for esterifying the rosin and wax composition with glycerol.<sup>107</sup>

Many substances have been added to rosin and glycerol preceding esterification in order to effect slight changes in the properties of the final product. Willard<sup>111</sup> used rosin, glycerol and rubber with a ferric oxide catalyst. Varnishes made from the resulting resin gave elastic films. Colophony, glycerol and polycarboxylic ketones were heated by Bruson<sup>112</sup> to obtain clear resins with high softening points. A rosin-aldehyde condensation product when treated with glycerol gives an oil-soluble resin.<sup>113</sup> A mixture of abietic acid and dihydroxydiphenylmethane dicarboxylic acids reacts with glycerol to give a product usable in nitrocellulose lacquers.<sup>114</sup>

**Crystalline Esters.** In a study of rosin esters, Wolff<sup>115</sup> found that a solution of ester gum in amyl acetate slowly deposited a crystalline precipitate. After three months the crystals were collected and proved to be glyceryl triabietate having a zero acid value, a saponification number of 54.4, a melting point of 172°C. and an average molecular weight of 955. Further supplies of the crystals were easily obtained by dissolving ester gum in warm ethyl acetate, adding a few drops

of benzene, cooling to 0°C. and seeding. By this procedure, a crop of crystals could be recovered in 3 days. As Wolff also obtained glyceryl triabietate on cooking metallic resinates with drying oils, he postulated as the varnish reaction that Glyceryl linoleate + Lead resinate  $\longrightarrow$  Glyceryl abietate + Lead linoleate.

An identical crystalline ester was obtained by Fonrobert and Pallauf<sup>116</sup> in a yield exceeding 10 per cent from a 50 per cent by weight solution of a pure rosin ester gum in hot acetone. Using samples of French, Spanish, American and German rosin and an English ester gum yields of 3 to 7 per cent were obtained. These crystals were found to be insoluble in ethyl alcohol (contrasting with glyceryl monoabietate and diabietate which are alcohol-soluble).

Crystals of glyceryl triabietate were prepared by Maly<sup>117</sup> by esterifying an alcoholic solution of abietic acid with glycerol. The crystals had a melting point of 125°C. and were soluble in alcohol and ether.

Nauroy<sup>118</sup> obtained crystals which were identified as 2-chloroglycerol diabietate. He dissolved abietic acid in a solvent consisting of equal parts of alcohol and xylene. After neutralizing with 0.5 *N* potassium hydroxide, the solution was refluxed 6 hours with a small proportion of trichlorohydrin. The precipitated potassium chloride was filtered off and the solution treated with carbon dioxide. The solvent was evaporated and the product crystallized from alcohol. The crystals had a melting point of 181°C., an acid value of 2.7 and a saponification value of 246.

#### MODIFICATION OF ESTERS

**Oxidation.** The addition of oxygen to ester gum has been proposed to modify its properties. Oxidation of ester gum raises its softening point and increases its solubility in many organic solvents. The temperature of ester gum during the reaction has to be controlled to avoid darkening the product. Schaal<sup>119</sup> used air to harden ester gum. Before treatment the rosin ester was powdered, mixed with a dehydrating agent (e.g., anhydrous sodium sulphate) and a catalyst (e.g., cobalt acetate or manganese borate). The whole mass was heated gradually to 100°C. and air passed through. After oxidation the inorganic substances were removed by water. The resulting material was directly soluble in oil.

Bradley<sup>120</sup> passed air over a thin layer of resin ester maintained at 60°C. After 4 days the softening point was raised from 90° to 121°C. The treatment increased the solubility of the ester gum in glycol mono esters and ethers. Slansky and Götz<sup>121</sup> reported that the properties of ester gum are improved by passing gases through the material while it is subjected to a silent electrical discharge.

Ozone has been used to hasten the drying of films produced from ester gum varnishes. Spence and Cochran<sup>122</sup> found that stoving a film in contact with ozone had no harmful consequences if ozone was absent during the first 10 minutes of the operation.

On long storage, surface oxidation of ester gum is great enough to change the color of varnishes made from it. For this reason ester gum stored in steel drums where it is one solid lump is better than that stored in wooden containers where

it is broken into small lumps because in the former case less surface is exposed to air.<sup>120</sup>

**Hydrogenation.** The resins resulting from the hydrogenation of rosin ester give films that are less brittle than those made from ester gum. As a consequence they are recommended for use in nitrocellulose lacquers. Basic pigments can be employed in conjunction with the hydrogenated esters.

It has been found that the reaction between esters and hydrogen is best carried out by having the esters in solution. The solvents suggested have been ethyl alcohol, butyl alcohol, benzene, toluene, ethyl acetate, petroleum naphtha and gasoline. To the solution there is added an activating acid (e.g., hydrochloric, phosphoric, acetic, formic). In addition to the acid, catalysts are used. The catalysts named have been nickel, palladium, platinum and chromites of copper, zinc and nickel. Under these conditions ethyl and methyl abietate have to be hydrogenated 4-5 hours to obtain a satisfactory product. To shorten the time still further the pressure must be greater than atmospheric. Pressures up to 2000 pounds per square inch have been suggested.

A procedure reported for the hydrogenation of the esters is as follows: 50 parts of ethyl abietate are dissolved in 148 parts of ethyl alcohol into which 2 parts of phosphoric acid have been put, 1 part of platinum oxide is incorporated and the solution is agitated under a pressure of 2 atmospheres at 25°C for 25 hours. By this treatment ethyl abietate takes up 70 per cent of the theoretical amount of hydrogen.<sup>124</sup>

It is possible to hydrogenate abietic acid before instead of after esterification. The properties of resins prepared by either method are similar.<sup>125</sup>

#### COPAL ESTERS

**Esterification of Copals with Glycerol.** Congo, Manila and Pontianac copals have the disadvantages which are inherent with resins possessing high acid number. For instance, varnishes made from them are likely to liver or stiffen if used with basic pigments to prepare enamels. The acid number of the copals is reduced by esterification in essentially the same manner as for rosin. Fossil resins esterified with glycerol are found to be compatible with basic pigments. In addition, varnishes made from ester copals form hard durable films that show good resistance to water and alkali.<sup>126</sup>

The esterification of copal resins is carried out by the same general methods as those used for colophony but experience is required to avoid difficulty when glycerol is added to the resin.<sup>127</sup> When a mixture of copal and glycerol is heated, it tends to polymerize to an infusible, spongy product. Examples of this phenomenon were observed in the author's laboratory while studying the esterification of Congo copal.<sup>128</sup> For instance Congo resin was run at 327°C. until sufficiently

<sup>128</sup> Carleton Ellis and L. Rabinovits, *Ind. Eng. Chem.*, 1916, 8, 406.

soluble in turpentine, and then glycerol added. A vigorous reaction occurred, yielding a spongy product which could not be fused on heating to over 360°C. On cooling, a porous resinous mass was obtained.

In the work of Gardner and Holdt<sup>129</sup> the same tendency to polymerize was encountered and a further study was made of the conditions under which this phenomenon occurs. The effect of metals, which some experimenters had thought to be the cause of polymerization, was eliminated by the use of glass apparatus.

In one of the preliminary experiments Gardner and Holdt heated Congo copal to 315°C and maintained it at that temperature for 30 minutes. During the heating the resin melted completely and appeared to be sufficiently cracked or run. The temperature was dropped to 280°C and 10 per cent of glycerol added. Then the temperature was increased to 290°C to bring about a combination of the resin acids and glycerol. In about 30 minutes the mixture suddenly became thick and gummy, then almost solid, swelling to such an extent as to fill the vessel almost completely. A spongy porous mass was obtained. The resin alone could not be made to polymerize even after prolonged heating in the absence of glycerol, hence the change must be attributed to the presence of the latter.

The polymerization of Manila and Pontianac copals was found to vary in speed but to resemble that of Congo. In each case, indication that gelling was about to take place was a sudden foaming, very similar to, but much more violent than the foaming which sometimes occurs when these resins are being melted.

From further experiments Gardner and Holdt concluded that polymerization would not occur if the resin is completely cracked previous to the addition of glycerol. Congo copal heated for one hour and 30 minutes at 280°C. and then treated with 10 per cent of glycerol did not polymerize. The excess of glycerol used was apparent in the cold solidified resin. Variation in the time of cracking showed that under the laboratory conditions polymerization would not occur if the resin was heated for more than 70 minutes. For a commercial plant, the length of time necessary to crack copal for successful esterification with glycerol must be determined for the individual apparatus at hand. From their work, the experimenters concluded that uncracked copals contain substances that have to be changed or volatilized by heat if polymerization is to be avoided.

Gardner and Holdt followed the progress of esterification by determining the acid number of the melt. Starting with Congo copal that had been cracked 75 minutes and had an acid number of 80 they added 6 per cent glycerol and maintained the mixture at 280°C. The condition of the resin and its acid number at ten-minute intervals is given in Table 38.

TABLE 38.—*Progress of Esterification of Copal.*

Time of Heating with Glycerol	Observations	Acid Value
10 minutes	Much glycerol left uncombined. Product cloudy	42
20 minutes	Some glycerol uncombined. Product somewhat cloudy.	36
30 minutes	Few drops of glycerol on side of flask at end of heating. Product clear.	30
40 minutes	Product clear.	23
50 minutes	Product clear.	19
1 hour	Product clear.	15
2 hours	Product clear but quite dark	5.5

The results show that esterification takes place rapidly at first. The acid value was reduced almost one-half during the first ten minutes of heating. The time

<sup>129</sup> H. A. Gardner and P. C. Holdt, *Circ., Paint Mfrs. Assoc.*, 1922, 151; *Chem. Abs.*, 1922, 16, 3217.

needed for esterification is therefore dependent upon the acid number desired in the product.

Excess glycerol and catalysts also hasten the reaction between copals and glycerol. If excess glycerol is added it must be volatilized after completion of esterification to insure a clear ester. The catalysts suggested were zinc and aluminum.

As a result of their work Gardner and Holdt offered the following procedure for the esterification of Congo copal. Bring the resin quickly to 315-325°C. and hold it there for 75-90 minutes or longer. Lower the temperature to 280°C. and add glycerol in slight excess (6-8 per cent). Raise to 292-295°C. and maintain at that temperature until the desired degree of neutralization has been obtained. After cooling, the ester is either poured into containers and stored or used directly to produce a varnish by heating with oils.

The disadvantages that accompany resins having high acidity have led a number of experimenters to investigate the esterification of copals. A procedure developed by Ellis<sup>130</sup> overcomes the difficulty of polymerization and produces a clear resin. This result was obtained by heating Congo copal for 3.5 hours at 315-325°C. and esterifying at 300°C. with 1/16 of its weight of glycerol in a covered aluminum kettle with a reflux condenser. Using a similar apparatus Ellis and Rabinovitz<sup>131</sup> esterified successfully dammar gum, Congo gum and Pontianac copal. An example from this work is as follows: 92 parts of fused Pontianac copal were heated with 8 parts of glycerol for 5 hours at 260-280°C. The acid number decreased from 74 to 34. A mixture of 100 kilos of cracked Congo copal and 15 kilos of redistilled copal oil were esterified with 5-6 kilos of glycerol by Terrisse.<sup>132</sup> The mass was heated at 280°C. until it was soluble in varnish solvents.

A treatment of copals with phenol and naphthalene before esterification has been suggested by Terrisse.<sup>133</sup> A mixture of copal and phenol or naphthalene is heated in an autoclave at 240-360°C. The phenol or naphthalene is removed finally by distillation and the resulting product is esterified with glycerol. In work by Krumbhaar,<sup>134</sup> on pretreatment of fossil resins, copals were masticated between steam-heated rollers to make them more soluble and fusible. After fusing, the resins are esterified with glycerol.

Brendel<sup>135</sup> proposed to esterify copals in the presence of drying oils. After cracking copals until they were free from foam, glycerol and linseed oil were added and the whole mass was heated to 310°C. Another proposal was the use of higher fatty acids with fossil resins and glycerol. The resin is dissolved in the acid and esterified at 250-280°C. in an inert atmosphere. Oil-soluble products are obtained.<sup>136</sup>

**Esterification of Copals by Other Methods.** Many of the other procedures suggested for esterifying resin have been used also for copals. For instance, the method of heating resins with high-boiling esters has been applied to the preparation of copal esters. This procedure is said to eliminate the thorough running that copals must be given before esterification. The avoidance of long heating at high temperatures produces a better-colored ester.

Esters that boil above 200°C. and whose resulting acids are volatile at that temperature are desirable. Following this principle, Hesse<sup>137</sup> employed alkyl or aryl esters of phthalic acid. Equal parts of copal and diethyl phthalate were mixed and the lower-boiling products removed by distillation. Other esters possessing the desired characteristics have been proposed. For instance, benzyl acetate or dibutyl phthalate is heated with copal at 300°C. for 4 hours. The acetic or phthalic acid is driven off as it is formed. The copal benzyl ester, melting at 43-52°C., has an acid number of 20.6 and a saponification number of 105. Products of alleged therapeutic value are prepared by heating compounds of the general formula,  $R_1CONR_2R_3$ , with copal. For example, acetamide and Congo copal react at 300°C. to give copalamide.<sup>138</sup> By the same general methods, Fonrobert and Lemmer<sup>139</sup> made Congo copal benzyl ester, Congo copal glycerol ester, Kauri copal benzyl ester and Manila copal butyl ester. The preparation of Congo glycerol ester is given as follows: 250 g. of Congo copal are heated with 147 g. of stearic triglyceride for 4 hours at 300°C. The copal is melted without vigorous frothing and at 275°C. a calm-boiling melt is formed. At the end of the esterification the stearic acid formed by the reactions is removed by heating at 260°C. under a vacuum of 10 mm. The residue consisted of 233 g. of Congo copal glycerol ester having an acid number of 1.5.

Copal may be treated with a number of other substances to give resins with special properties. Schaal<sup>140</sup> proposed that phenol, cresol, resorcinol, or naphthol be esterified with copal by heating at 180-210°C. The resulting resins were said to be usable in quick-drying varnishes. Scheiber<sup>141</sup> dissolved Manila copal in caustic alkali and mixed this with an alkaline solution of a polyhydroxy-carboxylic aliphatic acid (trihydroxystearic acid, dihydroxypalmitic acid). The resin is precipitated by adding hydrochloric acid. After filtering, the product is heated to 150°C. Since the resin is soluble in alcohol it has been suggested as a shellac substitute. It is rendered insoluble and infusible by heat. A rubber-like mass that is soluble in rubber solvents was obtained by Zobel<sup>142</sup> from creosote oil and copal. A mixture of hard-wood creosote oil and copal was heated and the resulting solution poured into petroleum naphtha.

**Esterification of Mixtures of Copal and Rosin.** Esterification of a mixture of copal and rosin overcomes the difficulties encountered with pure copal and at the same time a resin superior to ester gum is produced. The necessity of running copal completely creates problems that can be avoided if there is some rosin present. Also, the cracking is decisively aided and esterification of copal appears to be facilitated by the presence of rosin. The percentage of rosin present is generally greater than that of copal in order to keep the fusion point low. The addition of a hard fossil resin to rosin makes the final varnish films harder and more durable.

Mixed esters of copal and colophony were prepared by Schaal.<sup>143</sup> He proposed using glycerol, fruit sugar, phenol, cane sugar and mannitol with a mixture of

<sup>143</sup> E. Schaal, U. S. P. 501,446, July 11, 1893. See also E. Schaal, German P. 75,119 and 75,126, 1891; *Chem. Zentr.*, 1894, 2, 884.

copal and rosin. An example given by him is as follows: Fifty pounds of Manila copal are melted and an equal amount of rosin added. The temperature is raised to 180-210°C. and 6 pounds each of fruit sugar and glycerol are gradually added. The mixture is stirred constantly. The temperature is slowly increased to 280°C. and a vacuum of 100 mm. is maintained to remove aqueous vapors.

The esterification of mixtures of Congo copal and rosin was studied by Murray.<sup>144</sup> He found that 10 per cent of copal improved the hardness and toughness of the resulting ester without greatly increasing the difficulty of esterification. The process calls for heating a mixture of Congo and rosin in a covered kettle at 316-321°C. After the copal has dissolved completely in the rosin, the batch is cooled to 288°C. and 12 parts of glycerol are added. The reaction with glycerol is permitted to proceed until the desired acidity is reached. With the proportions 2 or 3 parts of copal to 1 part of rosin, the Congo resin tended to polymerize. The experimenter had less polymerization difficulty with an aluminum kettle than with one of copper.

Gammay added a powdered fossil resin to fused colophony and heated until a homogeneous solution resulted and then esterified the mixture with polyhydric alcohols.<sup>145</sup> Ellis and Weber<sup>146</sup> used a mixture of 4-5 parts of Congo with 1-2 parts of rosin. The mixture is heated until fusion occurs, glycerol added and esterification carried out at 270-290°C. The presence of calcium resinate aids the reaction.

Hocker<sup>147</sup> proposed that baking-varnishes be prepared from combinations of copals, rosin oil, gelatinizable vegetable oil, rosin and glycerol. The procedure for one method is given as follows: Two parts of rosin oil are heated with 1 part of Congo copal at 300°C. until the resin is completely fused. One gallon of glycerol for each 14 pounds of copal is added and the temperature maintained at 300°C. for one hour. The resin may be fused alone, with rosin or with tung oil before incorporation with glycerol and rosin oil. Also, the rosin oil may be incorporated with the drying oil and then heated with the esterified copal.<sup>148</sup>

#### APPARATUS EMPLOYED IN ESTERIFICATIONS

In the early attempts to prepare ester gum open vessels were used but the water formed during the esterification process vaporizes quickly and carries away much of the unreacted glycerol. This results in esters with high acid numbers. However, the water must be allowed to escape. The best procedure is to use a closed kettle with an air condenser of such length that it condenses the glycerol while permitting the steam to escape. By this method a large excess of glycerol is not needed (2 per cent excess is the general practice).

The esterification is carried out in both copper and aluminum equipment but aluminum is generally preferred. At 250°C. the esterification of rosin takes 3-5 hours. On cooling, boric acid is often added to inhibit the hydrolysis of the ester.<sup>149</sup>

The type of plant suggested by Schaal is shown in Figure 121. The kettle is equipped with a charging funnel and stirring device. A gooseneck connects the kettle to a receiver. The outlet pipe in the top of the receiver is connected with a pump so that a partial vacuum can be maintained.

kilos of varnish. The whole process is conducted in an atmosphere of carbon dioxide.<sup>102</sup>

In order to minimize fume loss in the running and esterification of natural resins, Frenkel<sup>103</sup> suggested the use of an apparatus heated indirectly with a high-boiling liquid medium (e.g., a mixture of phenyl ether and biphenyl) circulated through jacketed kettles. To obtain a good-quality ester an aluminum vessel is employed and an inert atmosphere is maintained.

#### ESTERIFICATION OF OTHER RESINS

The esterification of other resins has been undertaken with an idea of improving them for their present uses or of modifying them so that their field of application is widened. Although experimental details for the esterification of each resin will probably have to be determined individually, the methods discussed under rosin are generally applicable to other resins.

A number of these methods have been used to esterify shellac. Harries and Nagel<sup>104</sup> heated shellac with methyl alcohol in the presence of hydrochloric acid to obtain a methyl ester of shellac in the form of a yellow syrup. This syrup was purified by treatment with ether and crystallized from ethyl acetate. The final product melted at 149°C. and was soluble in alcohol, chloroform and benzene; slightly soluble in ether; and insoluble in petroleum ether. The same workers prepared a diacetyl ester by heating shellac with acetic anhydride.

Ethylene oxide, propylene oxide or corresponding halogen hydrins have also been proposed as esterifying agents for shellac. In these reactions the temperature is held at 60-100°C. and an increase in pressure is desirable. Boric acid and zinc chloride are catalysts for the esterification.<sup>105</sup>

The esterification of shellac with glycerol and the incorporation of the resulting resin in drying oil to make a baking enamel was suggested by Hocker.<sup>106</sup> Litharge and rosin added to glycerol and shellac aid in the production of a substance that can be used with oils.<sup>107</sup> Fusion with glycerol has been employed as a means for reconditioning shellac that has lost its fusibility through contact with bleaching powder. To accomplish this end, shellac is heated with glycerol at 160-220°C.<sup>108</sup>

The incorporation of shellac with glycerol, rosin and drying oils has been studied by Aldis.<sup>109</sup> The mixture is heated at 230-280°C. and then diluted with hot oil to give a long oil varnish. In another procedure glycerol and drying oil were replaced with ethylene glycol and castor oil to make a substance to be employed as a plasticizer in lacquers.<sup>100</sup>

Dammar is another resin which has been esterified with glycerol. In an experiment performed in the author's laboratory 50 parts of dammar and 5 parts of glycerol were heated with stirring at 250°C. for 30 minutes, yielding a dark-colored resin. The acid number fell from 39 to 12.5. Brendel<sup>101</sup> obtained best results with 2 per cent glycerol. The dammar and glycerol mix was heated at 180-270°C.

<sup>102</sup> H. Rahder, (*Farben.-Ztg.*, 1926, 31, 1742; *Brit. Chem. Abs.*, B, 1926, 554) has noted the need of an inert atmosphere in running and esterifying copals. See also Meister, *Farben.-Ztg.*, 1932, 37, 1604; *Chem. Abs.*, 1932, 26, 5776 and M. Bottler, *Kunststoffe*, 1913, 3, 85.

With this proportion of glycerol the final resin was free from the tackiness and brittleness of dammar and could be used for outdoor work. When the proportion of glycerol was increased to 8 per cent poor results were obtained.

Humphrey<sup>155</sup> esterified sandarac and pontianac gums with aliphatic chloroethers in presence of alkalis and monohydric alcohols. Esters of pimic acid may be prepared by heating under pressure with methyl alcohol, glycerol, or glycol in the presence of 3 per cent p-toluenesulphonic acid.<sup>156</sup> Pinene, turpentine and camphene can be converted into esters by using polycarboxylic anhydrides and aluminum chloride. A mixture of these substances is heated with a dehydrating catalyst (e.g., zinc chloride, boron trioxide) to give the ester.<sup>154</sup>

The conversion of cherry gum into a balsam-like material for varnishes was suggested by Voss.<sup>155</sup> The change is brought about by treating the gum with pyridine and amyl alcohol.

#### MISCELLANEOUS ESTERIFICATIONS

Natural substances of the type of montan wax have been esterified for the purpose of improving their properties so that they can compete with more expensive products used in polishes and in plastic compositions.

Montan wax may be esterified directly with glycerol. For example: 100 kg. of montan wax and 25 kg. of glycerol were heated until the wax had a low acid number. The time of reaction is shortened by using an autoclave, and sulphuric or hydrochloric acid as catalysts. The product had a melting point of 80-81°C. and had the property of raising the melting points of fats and waxes of lower melting points.<sup>156</sup> The wax may be bleached before esterification.<sup>157</sup> A wax, to be used in polishes, is prepared by partial esterification with glycerol and conversion of the remaining wax acids into metal salts by the addition of inorganic oxides.<sup>158</sup>

Glycerol may be replaced by monohydric alcohols to give waxes that can be employed as a basis for polishes. Excess alcohol is added and the unreacted portion removed by distilling.<sup>159</sup> Esterification products of ethylene glycol with such waxes have been used with fillers to make molded articles.<sup>170</sup> The esterification of bleached montan wax with glycerol in presence of a siccative, sulphur or sulphur compounds yields plastic compositions.<sup>171</sup>

Modification of the properties of montan wax may follow a different path. For example, the acids of the bleached wax may be reduced to alcohols and then esterified with organic acids. Non-aromatic monocarboxylic acids containing up to 25

carbon atoms (e.g., formic, acetic, stearic, palmitic, linoleic, abietic) have been recommended. By the proper selection of acid, waxes of desired melting point can be prepared, some of which exhibit physical properties similar to carnauba or beeswax.<sup>173</sup> Wax alcohols are proposed as esterifying agents for the distillation residues of fatty oils or acids. The residues are esterified with these alcohols and then neutralized with litharge. The product is diluted with turpentine or benzine to give a quick-drying varnish.<sup>173</sup> Esterified wax may be treated with a nitrogenous base (e.g., ethanolamine, piperidine, aryl- or alkyl amines) at 200°C. to convert part of the esters into amides. The products have been suggested for polishes and textile finishes.<sup>173a</sup>

Luther and Beller<sup>174</sup> have reported the formation of rubber-like masses from the heating of sulphur monochloride with a mixture of esters of polyhydric alcohols and unsaturated fatty acids, which were obtained from bleached waxes. A similar mixture may be treated with oxygen at 100°C. in the presence of litharge to give a product resembling linnoxyn.<sup>175</sup> Acids from montan wax, soya bean oil, linseed oil or tung oil were esterified with sorbitol to give a viscous drying oil.<sup>176</sup>

# Chapter 39

## Uses of Natural Resin Esters

### ESTER GUM VARNISHES

As was pointed out in Chapter 37 the use of rosin in oil varnishes is objectionable because of its acid nature, its softness, its lack of durability and its poor resistance to water. Ester gum represents a decided improvement over both raw and limed rosin with respect to water-resistance, durability and freedom from livering. The discovery that a good waterproof varnish can be made from a mixture of tung oil and ester gum has created a noteworthy change in varnish making. The result has been the substitution of ester gum for copals in the manufacture of spar varnishes. In fact, in numerous instances specifications for such varnishes have been modified so that ester gum is preferred to a hard fossil resin.

In addition to the wide use of ester gum in oil varnishes, this ester is employed to some extent in nitrocellulose lacquers. This is possible because ester gum is freely compatible not only with nitrocellulose but also with the majority of lacquer solvents and plasticizers. Coatings containing ester gum can be classified roughly into three groups, the first being the most important: 1. Oil varnishes, 2. Cellulose lacquers, 3. Spirit varnishes.

Other resin esters, particularly copal esters, are employed to some extent in oil varnishes, but ester gum is the most widely used resin ester.<sup>1</sup>

Ester gum in tung oil gives a much better varnish than the same resin in linseed oil. Tung oil appears to be more or less specific with the rosin ester, the oil imparting the required water-resistance to the coating. Hence, extensive use has been made of these two ingredients to manufacture a relatively cheap and yet entirely satisfactory varnish. In general an ester gum for oil varnishes should be pale in color and should have an acid number of about 6-10. According to Sanderson<sup>2</sup> there is some demand for ester gum with an acid number of 15, the slight acidity being necessary to assist the solvent action for polymerized tung oil and to increase the capacity for wetting pigments.

Some typical formulas for the preparation of oil varnishes in which ester gum is used have already been given in Chapter 38 in order to illustrate the esterification of rosin in the presence of drying oils.<sup>3</sup> There are of course many other varnishes in which ester gum is employed and a few are cited below.

A formula for the preparation of ester gum spar varnish containing free rosin, as employed in one varnish plant, is the following:

Tung oil	45 gal.
Linseed oil	5 gal.
Ester gum	100 lbs.
Rosin	50 lbs.
Litharge	1 lb.
Cobalt acetate	¼ lb.

<sup>1</sup> Advantages of copal esters over raw copals as pointed out by Meister (*Farben-Ztg.*, 1934, 39, 753; *Brit. Chem. Abs. B*, 1934, 803) include increased solubility in oils and thinners, improved weather-resistance of films, retardation of blooming and reduced livering with basic pigments. Copal-ester films bleach on exposure and do not display after-yellowing.

<sup>2</sup> J. McE. Sanderson, *Ind. Eng. Chem.*, 1934, 26, 711.

<sup>3</sup> See the section entitled "Esterification in Presence of Drying Oils" in Chapter 38.

To this mixture is added 50 per cent by volume of thinner composed of three parts of turpentine and one part of heavy benzine or mineral spirits.

The tung oil may be either raw or "prepared." The prepared oil is made by heating tung oil to 200°C. for 15 hours and then allowing it to settle to remove albuminous matter. The use of the small proportion of linseed oil is considered desirable because the varnish is said to be rendered more elastic thereby. The rosin is added to assist in blending the various ingredients. It is stated that the above proportion of rosin does not detract materially from the waterproof qualities of the varnish.

In preparing the varnish the linseed oil and tung oil are mixed and heated to 150°C. Litharge is then added and the temperature is raised and maintained at 230°C. to body the oil. When the oil begins to thicken, the rosin and ester gum are added and the temperature is raised to 300-315°C. The kettle is now pulled from the fire and allowed to cool. When the temperature has fallen to about 230°C. the cobalt acetate is added. The thinner is incorporated with the varnish at a temperature of 215°C.

This is of course by no means the only procedure for incorporating tung oil in varnishes. For instance in a method described by Riemann<sup>4</sup> the resin is not cooked with the oil from the beginning of the varnish-making operation. Instead, the oil is heated to 220-250°C. and then added to the resin which has been previously heated to 320-340°C. Driers and thinners are incorporated during the cooling operation.

A varnish, stated to be quick-drying, was prepared by Kessler<sup>5</sup> from the following ingredients:

Ester gum	7.5 per cent
Fused kauri gum	7.5
Tung oil	3.0
Boiled linseed oil	2.0
Benzene.	20.0
Toluene.	25.0
Xylene.	25.0
Butyl alcohol	10.0

This varnish is intended for use on metal work and is applied either by brushing or dipping.

The employment of copal esters in varnishes is exemplified by a coating preparation used by Terrisse.<sup>6</sup> Glycerol-esterified Manila copal is heated to 300°C. and then mixed with half its weight of linseed oil. When all the oil has been incorporated the temperature is raised to 310°C. and maintained at that point until the mixture has the desired consistency. Driers and thinners are added when the mix is being cooled. A paint said to have good covering power is obtained by grinding equal parts of the varnish and zinc oxide in a ball mill.

In addition to linseed oil and tung oil some of the lesser-known oils have been used favorably in ester-gum varnishes. For instance a varnish is prepared by heating a mixture of ester gum and paulownia oil to a high temperature and adding naphthols or naphthylamines and resinate driers.<sup>7</sup> Matumoto<sup>8</sup> obtained a paint by heating paulownia oil with fatty acids of the oil and with ester gum and then adding litharge and pigments. Experiments performed by Sward<sup>9</sup> indicated that an ester-gum varnish prepared with oiticica oil compares quite favorably with a similar varnish using tung oil.<sup>10</sup>

<sup>10</sup> Oiticica oil is extracted from the oval-shaped nuts of *Conepia grandifolia* (occurring in Brazil). It

The results of several investigations on the phenomena associated with varnish-cooking tend to show that ester gum retards the rate of polymerization of both linseed oil and tung oil.<sup>11</sup> The effect is only half as great with ester gum as with raw rosin, however.

**Properties of Ester Gum Films.** That the films formed by ester gums are satisfactory is well authenticated by their long-continued use. Many of the standard varnishes giving satisfactory service contain ester gum as the principal resin and some of these approximate the varnishes prepared from more costly fossil resins. The ester gum films are durable, show good resistance to abrasion and withstand outdoor exposure. When ester gum is mixed with basic pigments to make enamels the product does not liver or thicken.

An idea of the durability of ester gum varnishes may be obtained from the experimental results of Pearce<sup>12</sup> on outdoor exposure tests of various coatings. Some of these results are given in Table 39.

TABLE 39—*Exposure Tests of Varnishes.*

Composition	Gallons of Oil to 100 Pounds of Resin	First Appearance of Cracks in Days		Complete Failure in Days	
		Spring	Fall	Spring	Fall
Rosin-tung linseed . . .	20	29	28	106	100
Ester-tung linseed . . .	20	28	36	134	92
Kauri . . . . .	30	42	64	206	202
Manila-linseed . . . . .	30	36	22	120	203
Ester-tung . . . . .	30	58	100	183	208
Congo-tung linseed . . .	30	43	21	203	141
Rosin-tung perilla . . . .	30	43	36	100	71
Ester-tung . . . . .	40	71	64	134	203
Kauri-linseed . . . . .	40	42	78	141	252

The results indicate that the tung oil-ester gum varnish films do not crack as early as others and that a linseed oil-Kauri coating is the only one showing better results with respect to complete failure. The behavior of ester gum in rust-inhibitive primers was observed by exposure tests of one-year duration. With the pigments that were tried, ester gum proved to be a satisfactory resin.<sup>13</sup>

Experience has shown that films formed from ester gum compositions withstand well the action of water. All of the tung oil-ester gum varnishes obtained by Beegle<sup>14</sup> exhibited good waterproof qualities. However, those made from resins possessing acid numbers below 20 gave the best results when applied to glass and immersed in water 4 days. That the addition of ester gum improves the resistance of an oil film to water was deduced from the experimental work of Serb-Serbin.<sup>15</sup> In a study of permeability of coatings to moisture, Gettens<sup>16</sup> found that those produced from ester gum were among the best. Enamels containing ester gum are likely to chalk, blister and remain sticky for a long time under tropical conditions, probably because of the high humidity and temperature.<sup>17</sup> The difficulties were reduced by using an Albertol primer.

is said to resemble tung oil in many respects. See E. R. Bolton and C. Revis, *Analyst*, 1918, 43, 251; *Chem. Abs.*, 1918, 12, 2056. H. A. Gardner, *Circ., Am. Paint Mfrs. <sup>17</sup> Arnold, *Chem.-Ztg.*, 1932, 56, 55; *Chem. Abs.*, 1932, 26, 2606.

The yellowing of white enamels was studied by Munzert.<sup>18</sup> Starting with 4 pigments and 4 vehicles, coatings were made and applied to tin-plate panels. After exposure to diffused daylight for 4 days, one-half of the surface was covered with black paper and the panel exposed to sunlight for 14 days. Yellowing occurred in the half that was covered. With the ester gum enamels the yellowing was only slight.

**Properties of Copal Esters.** The properties of copal esters and the films formed from them are, as a whole, excellent. The copal esters are oil-soluble resins that give hard durable films. The coatings show good resistance to water and alkali. If the acid number of the ester is below 20 the esters are reasonably compatible with basic pigments.

In an experiment on resistance to alkalis, Gardner and Holdt<sup>19</sup> coated panels with varnishes containing copals and copal esters. These panels were immersed in 4 and 20 per cent caustic soda solution for 1 week. The copal varnishes were badly affected, being covered with a white scum. The coatings made with copal esters were not attacked by either solution. From a study of synthetic finishes, Staudermann<sup>20</sup> concluded that oil varnishes produced from copal esters are more durable than those obtained from ester gum but that the copals require a longer time to dry.

As has been stated previously, resins of high acid numbers liver or thicken when incorporated with basic pigments. Copal esters with low acid number would be expected to make enamels with pigments such as zinc oxide without this difficulty. Working on this problem, Gardner and Holdt<sup>21</sup> employed a copal ester to prepare varnishes having acid numbers of 4 and 25. Zinc oxide was ground with both varnishes. After standing a few hours the varnish possessing the higher acid number had thickened, but the other one was still of proper consistency after 8 months.

**Insulating Varnishes.** The utilization of ester gum for the manufacture of insulating varnish for coating electrical conductors has been proposed by many workers. Hocker<sup>22</sup> produced such coatings from rosin oil, glycerol, tung oil and ester gum. The product is thinned with benzene to give a quick-baking composition. The incorporation of a sulphide or selenide during the process of esterification is considered advantageous by Ohta.<sup>23</sup> An insulating varnish was prepared as follows: 1000 parts of rosin, 50-150 parts of glycerol, 5-30 parts of sodium sulphide or selenide and 1500 parts of tung oil containing an aluminum catalyst were heated to 240-300°C. After cooling, pigments and thinners were added.

An insulating varnish of different composition was made by Wright,<sup>24</sup> who used the reaction product of gum accroides, rosin and glycerol. Ester gum-tung oil varnishes were found to possess no advantage over rosin-tung oil ones for baked insulators, according to Mizushima.<sup>25</sup>

An electrical-insulating material has been made by cementing mica foil to paper. The glue suggested was produced by heating tung oil, Manjak asphalt, glycerol and

colophony to 250-300°C. until the oil polymerized and all volatile matter had escaped. The resulting mass was dissolved in benzene to form the cement.<sup>26</sup> A coating for insulating-tapes was proposed by Clark and Ruscetta.<sup>27</sup> The mixture consisted of ester gum (32-48 parts), montan wax (40-50 parts) and castor oil (10-28 parts).

**Special Uses of Ester Gum Varnishes.** One example of a coating requiring special properties is an anti-fouling paint, intended to retard the accumulation of marine growth on material in contact with sea water. The use of such paints to prevent marine borers from attacking wood was studied by Gardner.<sup>28</sup> Paints consisting of ester gum varnishes mixed with compounds of mercury or with cupric cyanide accomplished this special purpose. In further work, Gardner noted that certain white paints obtained from a benzol solution of ester gum were resistant to marine growths. An anti-fouling paint was prepared as follows: 650 pounds of ester gum were dissolved in 77 gallons of benzol, 10 gallons of spar varnish, 10 gallons of pine oil, a toxic substance and zinc oxide or Titanox were added and the mixture ground. After grinding, 48 gallons of benzol rubber solution were incorporated.<sup>29</sup> Ellis<sup>30</sup> employed rosin esters in coating compositions intended for application to concrete surfaces.

Ester gum mixed with tung oil, linseed oil, cobalt resinate, turpentine and pigments yields a composition that gives a flat finish to oilcloth.<sup>31</sup> A varnish, proposed for tin cans, is prepared from rosin, vegetable oil, a lead-free drier, glycerol, zinc and zinc oxide. The final product is applied to the interior of the can and baked at a high temperature. Since this coating contains no metals yielding colored sulphides, cans coated with it may be used for vegetables and fruits containing sulphur.<sup>32</sup> A varnish containing aluminum or brass powder in an ester gum vehicle was utilized by Bauer<sup>33</sup> to coat metal surfaces. After the coating has been applied, the metal is heated until the agglutinant begins to harden. The material is then subjected to pressure rolls to force the coating into the pores and inequalities of the surface. Finally, the varnish is baked until hard.

**Modification of Ester Gum Varnishes.** The incorporation of other substances with ester gum in varnishes is undertaken with the idea of changing in some way the characteristics of the final product. Mixing of other resins with ester gum during the preparation of a varnish yields a coating possessing some of the characteristics of each resin.<sup>34</sup> The film resulting from ester gum varnishes is hardened by adding a small amount of an oil-soluble phenol resin.<sup>35</sup> One method of incorporation is as follows: 15 kg. of Albertol 209L are mixed slowly with 20 kg. of varnish oil at 150°C. The temperature is raised to 260°C. and kept there until a specimen remains clear when diluted with an equal volume of thinner. After the addition of 100 kg. of heat-treated linseed oil, the temperature is maintained at 200°C. during the incorporation of ester gum (150 kg.) and then raised to 300°C. until the mixture is homogeneous. When the melt has cooled to 220°C. driers and thinners are added.

Gardner<sup>36</sup> heated a mixture of Aroclors with ester gum to produce a resinous

composition for oil varnishes or for nitrocellulose lacquers. A varnish may be prepared which has as a base a mixture of polystyrene with methyl tetrahydroabietate.<sup>37</sup> The inclusion of chloronaphthalenes, e.g., Halowax, in ester gum-tung oil varnish is said to improve its waterproofing characteristics.<sup>38</sup> According to Asser<sup>39</sup> the addition of a mixture of equal parts of phenol-formaldehyde and cresol-formaldehyde resin to ester gum raised its softening point from 68° to 110°C. The proportions used were 1 part of the phenol-resin mixture to 4.5 parts of melted ester gum fused at 150°C. until the melting point of the resulting resin is constant. It is reported that ethyl abietate when added to ester gum-tung oil varnishes improves the weathering properties of the final film but at the same time retards the rate of drying.<sup>40</sup>

Small amounts of antioxidants have been found to improve the quality of ester gum varnish films. For instance, Gardner and Sward<sup>41</sup> report that 0.1 per

FIG. 123.—Testing Rack on Roof of Author's Laboratory for Exposure Tests on Synthetic Resin Coatings.

cent of sulphur introduced into an ester gum varnish improves its durability. Increasing the amount of sulphur to 0.5 per cent produced harmful effects. Various compounds said to give an anti-aging effect in ester gum-drying oil varnishes include trihydrophenol, catechol, dimethyl ether of pyrogallol or guaiacol, diphenylguanidine and di-*o*-tolyl-guanidine.<sup>42</sup>

Although varnishes form the principal outlet for drying oil-ester gum mixtures small amounts have found use in other ways. Ester gum cooked in tung oil has been mixed with the customary ingredients and coated onto a felt base to make a floor covering.<sup>43</sup> A binder containing ester gum (50 parts), cumarone resin (50 parts), dibutyl tartrate (35 parts) and polymerized linseed oil (10 parts) has been suggested for cementing wood flour and cork in the manufacture of linoleum.<sup>44</sup>

Core oil (for foundry work) is sometimes comprised of rosin, linseed oil and thinner. McArdle<sup>45</sup> has employed ester gum, corn or soya bean oil and thinner to make a similar product.

An aqueous coating composition containing ester gum was proposed by Holman and Hooppaw.<sup>46</sup> The other ingredients in this paint were magnesium oxide, magnesium chloride, magnesium sulphate, pigments, tung oil and petroleum spirits.

#### RESIN ESTERS IN CELLULOSE LACQUERS

Cellulose lacquers have been utilized in situations where speed of application and drying are of importance. The oil-soluble resins are still widely used when spraying or dipping are impractical and drying-time is not of importance. In addition, resin varnishes enjoy another advantage in that they are generally cheaper. The characteristics of a nitrocellulose lacquer may be changed by the addition of a resin. The incorporation of resins in a lacquer increases the content of solids and improves the adhesion and gloss. Of the resins employed ester gum is one of the more popular because of its availability and because it is soluble in many lacquer solvents.

The properties required for ester gum to be incorporated in lacquers are approximately the same as those desired for oil varnishes. The resin should possess an acid number below 20 and a pale color. In addition, the ester should not contain any free glycerol, since the latter has a deleterious effect on the final film.

In preparing a nitrocellulose lacquer, the ester gum is first dissolved in a compatible diluent before it is incorporated in the lacquer. Benzene, toluene, ethyl acetate and butyl acetate are generally employed for this purpose. When the addition of an ester to a lacquer is being considered every ingredient that is to be incorporated must be studied. The quality of the nitrocellulose, the type of plasticizer, the character of the solvent and diluents determine as much as the ester the properties of the final coating. For instance, ester gum is not soluble in diacetone alcohol, ethyl lactate, Cellosolve or Cellosolve acetate.<sup>47</sup>

One nitrocellulose lacquer containing ester gum is described by Bogin.<sup>48</sup> The lacquer contains 0.5-1.0 pound of nitrocellulose and an equal weight of ester gum in 1 gallon of a solvent mixture comprising 10 per cent of a nitrocellulose solvent (b.p. 140-180°C), 10 per cent of cyclohexanol, 30 per cent ethyl acetate and 50 per cent of mixed benzene and toluene. In determining the optimum proportion of rosin-glycerol ester to solvent, Mowen<sup>49</sup> concluded that 16 pounds to 1 gallon of hydrocarbon (toluene) solvent give the best product. However, a proportion as high as 20 pounds of resin to 1 gallon of liquid is feasible. Symons<sup>50</sup> reports that the best ratio is equal parts of ester gum and nitrocellulose plus plasticizer amounting to 30 per cent of dry weight of the nitrocellulose.

Mention has been made that free glycerol in the rosin ester has a harmful effect on the final film. One method recommended to overcome this difficulty is to esterify with polyglycerol. The presence of this reagent is said to have no harmful effect on the final film.<sup>51</sup> It has been reported that the use of glyceryl diabietate in place of the triabietate in lacquers gives a film of good hardness and toughness.<sup>52</sup> The mixed esters of polyhydric aliphatic alcohols with higher fatty acids and resin acids have been employed as softening agents in oil-free cellulose ester or ether lacquers.<sup>53</sup>

Of the other esters of abietic acid, ethyl abietate appears to have a large field

of usefulness. It is said to act both as a resin and plasticizer. This would be an advantage because the necessity of adjusting the solvents and diluents to both resin and plasticizers would be eliminated.<sup>54</sup> A similar behavior was observed also by Johnston.<sup>55</sup> He found that ethyl abietate dissolves ester gum, elemi, mastic and rosin. If desired, however, it can be used in conjunction with other plasticizers. The films resulting from the addition of this ester to lacquers are said to be less tacky than those containing ester gum. The proportions recommended are 10 parts of half-second nitrocellulose to 26 parts of ethyl abietate. Employing the same ingredients, Bent<sup>56</sup> noticed that the films dried quickly and were durable. Kesler<sup>57</sup> reported that many esters of abietic acid resemble ethyl abietate in their combined plasticizer and resin effect. These resins could be substituted for plasticizers such as dibutyl phthalate.

Some esters of abietic acid other than those previously mentioned have been suggested for addition to cellulose lacquers. For instance, the hydroxyalkyl esters, which are made with alkylene oxides and abietic acid, can be used as softening agents for lacquers.<sup>58</sup> Chlorinated rosin is also reported to be a good resin for adding to nitrocellulose coatings.<sup>59</sup> In some cases improved films result when another resin is employed in addition to ester gum in nitrocellulose lacquers. Dammar added to an ester-gum-containing lacquer seems to increase the adhesiveness of the coating and to decrease chalking. A composition of this sort proposed by Gilbert<sup>60</sup> contains the following substances:

	Per Cent by Weight
Low-viscosity nitrocellulose . . .	10.
Dammar resin . . . . .	2 5
Ester gum . . . . .	2.5
Castor oil . . . . .	3 0
Dibutyl phthalate . . . . .	3.
Antimony oxide . . . . .	15.
Solvents and diluents . . . . .	64.

A mixture of ester gum, 1.5-3 parts and a cumarone-indene resin, 1 part, has been recommended for addition to nitrocellulose to yield a non-blushing film.<sup>61</sup>

Gardner<sup>62</sup> found that methyl or butyl esters of shellac give good elasticity and gloss to the lacquer film. These esters act not only as resins but may replace also the plasticizers in cellulose ester compositions. The esterification of Catavia resin (a balsam from Panama) gives a product that possesses possibilities as a varnish resin.<sup>63</sup>

Barrett<sup>64</sup> proposed the inclusion of hydroquinone to inhibit atmospheric oxidation of nitrocellulose films. Phosphorescent coatings can be produced by grinding luminous salts with rosin esters. This mixture is then incorporated with a plasticized cellulose lacquer to give the final product.<sup>65</sup>

Of the cellulose esters, the nitrate has the largest use as a lacquer constituent.

<sup>65</sup> J. A. Beavis, British P. 299,228, 1928; *Brit. Chem. Abs. B*, 1929, 64.

Because of its inflammability and tendency to hydrolyze, attempts have been made to replace it with other esters or ethers. Dreyfus<sup>66</sup> has reported that ester gum may be used with low-viscosity methyl, ethyl and benzyl cellulose. One such lacquer contained the following ingredients; ethyl cellulose (10 parts), ester gum (5 parts), toluene (90 parts), liquid paraffin (1.5 parts) and dibutyl phthalate (0.5 part).<sup>67</sup>

Ester gum has been incorporated in lacquers which are aqueous emulsions of cellulose esters. An example of one such lacquer is as follows: 0.25 part of sodium oleate in 40 parts of water are added to a solution containing nitrocellulose (12 parts), ester gum (4 parts), tricresyl phosphate (6 parts), chrome yellow (8 parts) and cyclohexanone (60 parts). The compositions are said to dry to hard transparent films.<sup>68</sup> Aqueous dispersions of ester gum are obtained by adjusting and holding the hydrogen ion concentration of the system within certain limits. This may be accomplished with colloidal clay or bentonite.<sup>69</sup>

Compositions containing rosin esters and a cellulose ester have been proposed for purposes other than lacquer coatings. Ethyl abietate has been suggested as an agent for replacing linseed oil in coating compositions used in the manufacture of floor covering. The resulting linoleum is said to be flexible and resilient. Objectionable odors which develop from plasticizing-oil are eliminated.<sup>70</sup> An illustration of a recommended composition follows:

Soluble nitrocellulose	..	28	parts	by	weight.
Ethyl abietate		31	"	"	"
Tricresyl phosphate		7	"	"	"
Wood flour		34	"	"	"

In another proposal a mixture of ester gum, benzylcellulose, dicresylm and cork dust is utilized to prepare a flooring composition.<sup>71</sup>

Thin waterproof sheets are prepared from a solution containing nitrocellulose, ester gum, dibutyl phthalate and paraffin. The solution is dried at a temperature higher than the melting point of the wax.<sup>72</sup> A homogeneous smokeless powder was obtained by Norton<sup>73</sup> from nitrocellulose (60-90 parts), ethyl, phenol or benzyl abietate (5-25 parts) and nitroglycerine (5-30 parts). Ester gum has been included in a nitrocellulose bonding material for making floor tile of finely divided cork.<sup>74</sup>

#### NITROCELLULOSE-ESTER GUM-OIL COMPOSITIONS

The modification of cellulose lacquers by the addition of drying oils has been suggested in attempts to obtain improved coatings. Of course, for such incorporation, care must be taken not only to obtain a homogeneous solution of the various ingredients (apart from pigments) but that such a solution dries evenly in films without separation of the cellulose ester, an occurrence which would result in a slow-drying gel.

Studying the addition of tung oil to ester gum-nitrocellulose lacquers, Flood, Booth and Beisler<sup>75</sup> concluded that it is possible to obtain tough water-resistant

films from these compositions. These workers found that the addition of raw tung oil to the lacquer containing ester gums yielded coatings that gave opaque films of low tensile strength. The use of bodied tung oil produced better results but the final films were red in color. By heating the ester gum with tung oil and then adding to nitrocellulose, the resulting composition possessed the desired properties. Ester gum, tung oil and glycerol were refluxed at 275°C for 2 hours and steam passed through the mixture 45 minutes at 180°C. As much as 30 per cent tung oil was incorporated with the rosin ester. This resin was dissolved in a thinner and added to the nitrocellulose solution. One composition contained the following substances (by weight):

Dry nitrocellulose	19.2 parts
Ethanol	8.2 "
Amyl acetate	30.0 "
Benzene	13.5 "
Ester gum-tung oil resin	5.7 "
Ethyl acetate	6.8 "
Diacetone alcohol	3.0 "
Xylene	13.5 "

Exposure tests on wooden panels indicated that the presence of tung oil increases the durability of the films. From his experimental work, Kolke<sup>76</sup> found that the combination of a rosin ester-tung oil varnish with a butyl acetate solution of nitro-cotton yielded a good lacquer.

A method of preparing an ester gum-tung oil-nitrocellulose composition is described by Swartz.<sup>77</sup> Fifty pounds of ester and 15 gallons of oil are heated to 200°C, 4 pounds of litharge added and the temperature raised to 280°C. At 290°C 50 pounds more of ester gum are added. Manganese resinate is incorporated at 260°C. and toluene at 175°C. This composition is added to an equal volume of a solution made from 2 pounds of dry, half-second R. S. Cotton, 1 gallon of butyl acetate and 21 per cent of plasticizer. The final product may be applied as a spray or thinned with toluol, butanol or butyl propionate for brushing. When sprayed onto wood the coating will dry to touch in 15 minutes and hard enough to handle in 2 hours.

In some instances linseed oil has been employed in this type of coating but for most purposes tung oil has been found to give the best results. A flat varnish containing linseed oil was prepared by Burgemeister<sup>78</sup> by melting the ingredients together at 280-300°C. As an example, ester gum (250 parts), linseed oil (500 parts) and ethyl cellulose (250 parts) were heated until oil and resin dissolved. Jenkins<sup>79</sup> added  $\beta$ -hydroxy methyl propionate to a linseed oil lacquer. One such composition contained nitrocellulose (12 parts), butyl propionate (5 parts),  $\beta$ -hydroxy methyl propionate (10 parts), butyl alcohol (25 parts), ester gum (10 parts), linseed oil (10 parts), tricresyl phosphate (3 parts), xylene (20 parts) and turpentine (5 parts).

An oxidized ester gum-linseed oil mixture was proposed by Bonney and Egge<sup>80</sup> for addition to lacquers. The mixture consisted of linseed oil (3 parts) and ester gum (1 part). This was heated to 115°C. until the resin dissolved; then a drier was added. The mass was aerated for 25-30 hours at 80°C. until it became viscous. The unoxidized constituents of the batch were extracted by petroleum naphtha. Thirty parts of the product were mixed with cellulose nitrate (10 parts) and solvent (60 parts) to give clear protective coatings. Another composition consists of linoloxyn, ester gum, cellulose acetate, tricresyl phosphate, castor oil, sol-

vents and diluents.<sup>61</sup> Ellis<sup>62</sup> employed a destructively-distilled castor-oil condensation product for incorporation into pyroxylin lacquers containing ester gum.

Rosin ester, cellulose derivatives and oil have been added to plastic compositions. Griffiths<sup>63</sup> prepared such a combination from nitrocellulose (15-20 parts), ester gum (5-9 parts), castor oil (1-5 parts), solvent (66-79 parts) and wood flour (15-30) parts. Another plastic composition is made from nitrocellulose, bodied linseed oil, ester gum, solvents and powdered slate.<sup>64</sup>

A thermoplastic composition, produced from a mixture of glycerol, rosin, tung oil and stearin has been proposed by Hadley.<sup>65</sup> The mixture is heated until the oil is polymerized, the rosin esterified and the volatile matter driven off. The resulting composition is used with mica to form electrical insulators. A composition containing ester gum, nitrocellulose, castor oil and lampblack has been suggested as a printing ink.<sup>66</sup>

**Properties of Nitrocellulose-Resin Films.** As was already stated, the incorporation of esters with lacquers alters the characteristics of the coating composition. Effect of esters upon the time of drying and method of application has been mentioned previously. The largest changes in the final coating are probably those with respect to adhesiveness and gloss.

Tests on the adhesiveness of nitrocellulose films were carried out by Gardner and Van Heuckeroth.<sup>67</sup> A number of lacquers and resin-lacquer compositions were coated onto different surfaces. After drying, the coating was stripped off.<sup>68</sup> The load (in grams) required to remove the film from the material is taken as a measure of the adhesiveness of the film. In Table 40 are given the results of a lacquer containing 9 per cent of dibutyl phthalate and one consisting of 100 parts of cotton base<sup>69</sup> and 25 parts of ester gum dissolved in toluene (25 parts), toluene (50 parts) and dibutyl phthalate (10 parts), after each had dried 6 days.

TABLE 40.—Adherence of Lacquers to Various Surfaces.

Material	Galvanized	Black	Glass	Wood	Tin	Aluminum
	Iron	Iron				
Lacquer . . . . .	280	20	320	460	0	0
Ester gum-lacquer . . .	600	200	400	480	100	20

Results are expressed as load in grams required to strip coating from material.

In testing lacquers, Merz<sup>70</sup> varied the proportion of ester gum from 0 to 100 per cent (based on total solids). As the percentage of rosin ester increased the film became more brittle, but up to 70 per cent ester gum had comparatively slight effect on the durability (by accelerated methods). However, Duncan, Wiggam and Davey<sup>71</sup> concluded from their work on light-absorption by lacquer films that ester gum was affected by ultraviolet light. This is not a large factor however in lacquers containing pigments because these solids protect the film by rendering it opaque.

After studying color, gloss, binding power, elasticity and durability of lacquers

containing various resins, Toeldte<sup>92</sup> decided that ester gum was among the best for incorporation with nitrocellulose. Experiments on the tensile strength of nitrocellulose films by Jones and Miles<sup>93</sup> showed that lacquers containing ester gums had high tensile strength. These workers found that the properties of the nitrocellulose solvents and plasticizers employed affected the characteristics so much that these as well as the ester gum have to be considered in judging a lacquer.

#### SOLUTIONS OF RESIN ESTERS

Solutions of esters without drying oils have been proposed for use as coating compositions. If the solvent is volatile, waterproof coatings are quickly formed. These compositions of course do not exhibit all the desirable properties of an oil varnish. However, they are practical for certain purposes. The use to which the coating is to be put generally determines the solvent employed. Acetone is one solvent that has been suggested. Woodford<sup>94</sup> dissolved ester gum (1 part) in acetone (3 parts) to produce a liquid that would adhere well to paraffin paper and dry in 10 seconds. A solution comprising equal parts of ester gum, rosin and acetone was used to size and waterproof fabrics.<sup>95</sup> To make a photographic film non-static, Seel<sup>96</sup> coated it with a 3 per cent solution of ester gum in acetone. Esters of 9,11-octadecadiene-1-carboxylic acid with glycerol were used by Scheiber<sup>97</sup> in conjunction with ester gum to prepare vehicles for printing inks. A bronze printing ink, which contained finely divided metal, ester gum and terpineol was made by McElroy and Clarke.<sup>98</sup> A turpentine solution of ester gum was included in a metal polish by Jones and Harding.<sup>99</sup> The polish was said to leave a protective film not easily removed by rubbing.

A carbon paper is obtained by coating paper with a composition consisting of resin esters and coloring matter dissolved in a volatile liquid.<sup>100</sup> The resinates of amino alcohols, employed with volatile solvents, are suggested as sizing for textiles or cellulose pulps.<sup>101</sup> A solution of an ester gum has been used for sealing the edges of safety glass. The solvent chosen should also soften the edges of the central layer.<sup>102</sup>

#### MIXTURES OF ESTER GUM AND RUBBER

Ester gum has been mixed with rubber to prepare materials whose properties and uses depend upon relative proportions of ingredients and fillers. A plastic adhesive rubber composition is produced by heating ester gum (10 parts) and vulcanized rubber (4-15 parts) for 6 hours in an autoclave at 175°C.<sup>103</sup> Ester gum dispersions in reclaimed rubber (100:50-200) can be diluted with a solvent (e.g.,

gasoline, carbon tetrachloride) to obtain an adhesive.<sup>104</sup> A rubber composition for shoe soles was made from esters of rosin, rubber, gasoline, fibrous material, sulphur, lampblack and resin emulsion.<sup>105</sup> The addition of 5-30 per cent ethyl abietate (as a plasticizer) to a mixture of gutta-percha and deproteinized rubber yields an insulating material that can be used for high-frequency cables.<sup>106</sup> Ethylene oxide-abietic ester has been employed with a butadiene polymerization product in the preparation of insulated cables.<sup>107</sup>

A cement consisting of solid chlorinated naphthalene (Halowax), ester gum and rubber latex has been suggested as a bonding agent for glass, metal and wood.<sup>108</sup> The cement is fused and applied to articles that have been heated to 110°C.

The use of a synthetic resin in chewing gum is of course contingent on the absence of any undesirable flavor. Weber<sup>109</sup> found that ester gum, after treatment with dry steam at 150°C. could be employed successfully for this purpose. One chewing gum proposed contained 25 pounds of chicla to 10 pounds of ester gum. A chicla substitute was prepared from natural rubber and the rosin esters of glycerol, glycol or naphthol.<sup>110</sup> A paraffin wax-rubber base mixed with ester gum gives a bland tasteless mass when heated to 145°C. The consistency of the chewing gum is controlled by the proportion of ester.<sup>111</sup> The benzyl ester of abietic acid, which is a resinous material softer than ester gum, was proposed for use in chewing gum and as a waterproofing agent for paper.<sup>112</sup>

#### ESTER GUM IN PAPER COATINGS

Among the numerous materials which have been proposed for impregnating paper for various reasons (waterproofing, preparing stencils, etc.), mixtures containing ester gum have found some use. For instance, a waterproofing composition was prepared by Pearsall<sup>113</sup> from petrolatum wax (15-95 parts) and ester gum (5-85 parts). The coating is non-tacky and will not stain white paper. It is said to be good for waterproofing fuses. Acoustic diaphragms, constructed of cloth or paper, are made air-impervious and water-repellant by a mixture composed of equal parts of tung oil and ester gum.<sup>114</sup> A composition, proposed for waterproofing paper, contains a cellulose ester, ester gum, wax, plasticizer and solvent.<sup>115</sup>

Certain esters have been included in coatings for application on thin tissue paper to make stencil sheets. One such mixture consists of mineral wax and a polyhydric ester of bleached montan wax. Another one was produced from cellulose esters, naphthenic acid glycerides and a heavy hydrocarbon oil.<sup>116</sup> A solution of ester gum, turpentine and castor oil was coated onto backing-sheets for duplicating-machine stencil sheets.<sup>117</sup> Decalcomania paper with a design thereon is provided with a coating containing nitrocellulose, ester gum, plasticizer and solvent.<sup>118</sup>

A fusible composition, which on heating is intended to be transferred from the original paper (dry transfer), was obtained by Lawrence<sup>119</sup> from a mixture of rosin ester, wax, castor oil, cadmium selenide and solvent. Another combination used for the same purpose is composed of ethyl cellulose, ethyl abietate, cumarone, gold bronze, the monoethyl ether of diethylene glycol (Carbitol) and castor oil.<sup>120</sup> Ethyl and butyl abietate have been mentioned as plasticizers for phenolic resinoids to be employed as cements in the making of laminated material from paper.<sup>121</sup>

#### MISCELLANEOUS USES OF ESTER GUM

Ester gum has been added to plastic compositions to replace more costly materials or to modify in some manner the properties of the product. Generally ester gum does not constitute a large percentage of the total mass. One such plastic composition proposed by Hull<sup>122</sup> contained casein (50 parts), furfural (5 parts), ester gum (5 parts), slate dust (40 parts). The mass was molded at 100°C. for 50 minutes under a pressure of 3 tons to the square inch. Another plastic mass includes ester gum and kieselguhr among its ingredients.<sup>123</sup> The esterification product of copal with polyhydroxy fatty acids has been suggested as a binding medium in the making of phonograph records.<sup>124</sup>

The addition of ester gum to a composition containing camphor and nitrocellulose lowers the modulus of elasticity of the resulting celluloid.<sup>125</sup> A mixture of this type containing a resin ester has been employed as a shoe-upper stiffener (e.g., box toes).<sup>126</sup>

The esterification of rosin and phenol in the presence of mineral acids yields a resin insoluble in water. It is rendered soluble by sulphonation, the resulting product being employed as a tanning agent.<sup>127</sup>

Esters of abietic acid and montan wax may be used as emulsifying, cleansing and wetting agents. Triethanolamine abietate has been proposed as emulsifier in the preparation of a pyrethrum emulsion.<sup>128</sup> The acids of crude or treated montan wax were esterified with aliphatic or aralkyl alcohols to give materials which may be utilized as wetting, emulsifying, cleansing and sizing agents.<sup>129</sup> A mixture of hexamethylenetetramine (1-25 per cent) and ethyl abietate (75-99 per cent) was employed as a soldering flux by McBride.<sup>130</sup> Heptaldehyde and undecylenic acid have been obtained from a mixture of raw castor oil and ester gum destructively distilled *in vacuo* at 300-340°C.<sup>131</sup>

## Chapter 40

### The Diene Synthesis

The Diels-Alder reaction has opened up a new field of synthesis of such compounds as terpenes, sesquiterpenes, camphors, alkaloids, and partially hydrogenated benzene derivatives. The direct application of this reaction to the production of resins has taken place only in certain isolated instances. Indirectly, however, the reaction has served to interpret or re-interpret mechanisms which could not otherwise be characterized and to elucidate structures, particularly as regards to whether a conjugated system does or does not exist.<sup>1</sup> The diene synthesis, as the Diels-Alder reaction is usually termed, probably is designed to play an important role in the field of synthetic resins, both in the production of special types or qualities of resins and in the study of various resinifying reactions. For this reason it has been deemed desirable to present a rather complete consideration of the chemistry involved in the formation of the products of diene synthesis (so-called adducts), a discussion of which embraces the greater part of the text of this chapter. In 1906 Albrecht<sup>2</sup> described several reactions between quinones and cyclopentadiene. He found that either one or two molecules of cyclopentadiene would combine by straight addition with benzoquinone but could not assign any satisfactory constitution to the resulting products. Somewhat later, it was noted that isoprene could likewise be condensed with benzoquinone<sup>3</sup> by heating in a sealed tube at 120-180°C. for 5 to 6 hours. The resulting product was a white crystalline substance, which added two mols of bromine and which formed a dioxime. It was suggested that the isoprene added 1,4 to the quinone and the provisional formula was assigned as

<sup>1</sup> For the use of maleic anhydride and citraconic anhydride, for example, in the purification or the isolation of new isomers and in the elucidation of the structures of ergosterol and Vitamin D, see A. Windaus, K. Dithmar, H. Murke and F. Suckfüll, *Ann.*, 1931, 485, 91; *Brit. Chem. Abs. A.*, 1931, 1051. A. Windaus, A. Lüttringhaus and M. Deppe, *Ann.*, 1931, 489, 252; *Chem. Abs.*, 1932, 26, 1016. A. Windaus and A. Lüttringhaus, *Ber.*, 1931, 64, 850; *Chem. Abs.*, 1931, 25, 4007. A. Windaus, *Proc. Roy. Soc.*, 1931, 108B, 568; *Brit. Chem. Abs. A.*, 1931, 1098. W. Stoll, *Z. physiol. Chem.*, 1901, 202, 232; *Chem. Abs.*, 1932, 26, 734. Z. Nakamiya, *Z. physiol. Chem.*, 1931, 203, 255; *Chem. Abs.*, 1932, 26, 1295.

For the use of maleic anhydride to identify the diolefins in the lower fractions of vapor-phase-cracked gasoline, see S. F. Birch and W. D. Scott, *Ind. Eng. Chem.*, 1932, 24, 49. J. C. Morrell, C. G. Dryer, C. D. Lowry, Jr., and G. Egloff, *ibid.*, 1934, 26, 655; in the determination of divinyl in the presence of butylenes, see I. F. Suknevich and A. A. Chilingaryan, *J. Applied Chem. (U.S.S.R.)*, 1931, 4, 724; *Chem. Abs.*, 1932, 26, 941; and in the estimation of isoprene from rubber, see H. L. Bassett and H. G. Williams, *J.C.S.*, 1932, 3234. An apparatus for the determination of diolefin hydrocarbons in gas is described by A. A. Korotkov, *Sintet. Kauchuk*, 1933, 4, 23; *Chem. Abs.*, 1934, 28, 3028 and by H. Tropach and W. J. Mattox, *Ind. Eng. Chem., Anal. Ed.*, 1934, 6, 104.

For the characterization of the dimethylbutadienes by maleic anhydride, E. H. Farmer and F. L. Warren (*J.C.S.*, 1931, 3221) have found that the 1,3-, the 1,4- and the 2,3-dimethylbutadienes add quantitatively; the 1,3-dimethyl and the 1-methyl polymerize slightly and the 1,1-dimethyl polymerizes completely.

<sup>2</sup> W. Albrecht, *Ann.*, 1906, 348, 31; *J.C.S.*, 1906, 90 (1), 674.

<sup>3</sup> H. von Euler and K. O. Josephson, *Ber.*, 1920, 53, 523; *Chem. Abs.*, 1920, 14, 3342.

Diels, Blom and Koll<sup>4</sup> determined the structure of the reaction product of dimethylisoprene (2,4-dimethyl-1,3-pentadiene) with ethyl azocarboxylate to be diethyl 3,3,5-trimethyl- $\Delta^4$ -tetrahydro-1,2-pyridazine-1,2-dicarboxylate.

They suggested at the time that cyclopentadiene in Albrecht's reaction<sup>5</sup> reacted as a conjugated system with quinone. Later Diels and Alder<sup>6</sup> extended the scope of the reaction of the addition products of the dienes and since that time the method has been known as the "diene synthesis" or the Diels-Alder reaction.<sup>7</sup> It involves a system of conjugated double bonds reacting with the grouping

in such a manner that the conjugated double bonds are opened up at the 1,4 position and become attached to or saturate the ethylenic bond of the  $\alpha\beta$ -enal with the formation of carbon-carbon unions. The reaction of butadiene with acrolein may be represented as follows:

the final product being  $\Delta^4$ -tetrahydrobenzaldehyde.<sup>8a</sup>

This system of conjugated double bonds may be in a straight chain (butadiene, isoprene, dimethylbutadiene or myrcene), in a cyclic structure (cyclopentadiene, cyclohexadiene,  $\alpha$ -phellandrene or anthracene) or in a heterocyclic structure (furan, pyrrole). The  $\alpha\beta$ -enal grouping ( $-\text{C}=\text{C}-\overset{\text{O}}{\parallel}{\text{C}}=$ ) may be in a straight chain (acrolein, acrylic acid, crotonaldehyde) or in a ring (quinone, maleic anhydride,<sup>9</sup> itaconic anhydride or citraconic anhydride). Cyclopentadienone stands in rather an anomalous position in that it fits into both classifications. It should undergo auto-reaction; this was found to be the case in the phenyl-substituted derivative.

<sup>4</sup> O. Diels, J. H. Blom and W. Koll, *Ann.*, 1925, 443, 242; *J.C.S.*, 1925, 128 (1), 976.

<sup>5</sup> W. Albrecht, *loc. cit.*

<sup>6</sup> O. Diels and K. Alder, *Ann.*, 1928, 460, 98; *Chem. Abs.*, 1928, 22, 1144.

<sup>7</sup> For reviews on the diene synthesis, see K. Alder, "Die Methoden der Dien-synthese," Abt. I, Teil 2/11 in E. Abderhalden's "Handbuch der Biologischen Arbeitsmethoden," Urban & Schwarzenberg, Berlin and Vienna, 1933, 3079, and O. Diels, *Z. angew. Chem.*, 1929, 42, 911; *Chem. Abs.*, 1930, 24, 356. See also O. Diels and K. Alder, *U. S. P.* 1,944,731 and 1,944,732, Jan. 23, 1934, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1934, 28, 2010, 1937, British P. 300,180, 1927; *Chem. Abs.*, 1929, 23, 3476. German P. 526,163, 1927; *Chem. Abs.*, 1931, 25, 4283.

<sup>8a</sup> Reaction of  $\alpha$ -phenylbutadiene with acrolein forms 2-phenyl- $\Delta^4$ -tetrahydrobenzaldehyde. See E. Lehmann and W. Paasche, *Ber.*, 1935, 68, 1146.

<sup>9</sup> P. Pfeiffer and T. Böttler (*Ber.*, 1918, 51, 1819; *Chem. Abs.*, 1919, 13, 1471) have discussed the quinoidal nature of maleic anhydride.

More recently, it has been shown that the acetylenic linkage will also react with the dienes. Mention has already been made of the reaction between certain azo compounds and conjugated diene hydrocarbons.

It may readily be seen that, with this form of synthesis, numerous types of compounds may be built up. The structures, which will be considered, are: first, the reaction of the dienes in a straight chain; second, the dienes in a cyclic system (both homo- and heterocyclic); and finally, the action of higher polyenes.

#### ACYCLIC BUTADIENOIDS

6-Methyl- $\Delta^3$ -tetrahydrobenzaldehyde\* is obtained by the action of butadiene on crotonaldehyde. By using maleic anhydride<sup>10</sup> (in place of the aldehyde) with butadiene, the cis- $\Delta^4$ -tetrahydro-o-phthalic anhydride is obtained.

Brooks and Cardarelli<sup>11</sup> prepared a light-colored resin by heating this acid (or anhydride) with glycerol.

Benzoquinone having two  $\alpha\beta$ -enal groupings may react with one or two mols of the diene to give rise to  $\Delta^{2,6}$ -tetrahydro-1,4-naphthoquinone and  $\Delta^{2,6}$ -octahydro-anthraquinone, respectively.<sup>12</sup> The tetrahydronaphthoquinone, formed from benzoquinone and butadiene, reacts with a second mol of the diene to yield the octahydroanthraquinone, as represented below:

The octahydroanthraquinones, however, are capable of isomerization when heated with acid or with alkali. When treated with alcoholates they yield hexahydroanthrahydroquinones which may be dehydrogenated to hexahydroanthraquinones.<sup>13</sup>

\* When this aldehyde (or others of like nature) is treated with acetone and sodium methoxide aldolization takes place. By dehydration, tetrahydromethyl-benzalacetone, a perfume ingredient, is obtained; see O. Diels and K. Alder, U. S. P. 1,891,043, Dec. 13, 1932, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1933, 27, 1891. German P. 555,398, 1929; *Chem. Abs.*, 1932, 26, 3075.

<sup>10</sup> O. Diels and K. Alder, *Ann.*, 1928, 460, 98; *Chem. Abs.*, 1928, 22, 1144.

<sup>11</sup> B. T. Brooks and E. J. Cardarelli, U. S. P. 1,860,730, May 31, 1932; *Chem. Abs.*, 1932, 26, 3945.

<sup>12</sup> O. Diels and K. Alder, *loc. cit.* K. Alder and G. Stein, *Ann.*, 1933, 501, 247; *Chem. Abs.*, 1933, 27, 2441. For the addition of diazomethane to quinones, see L. F. Fieser and M. A. Peters, *J.A.C.S.*, 1931, 53, 4080.

<sup>13</sup> A. Lüttringhaus, H. Neresheimer and W. Schneider, German P. 494,443, 1928, and addn. 554,878, 1929, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1930, 24, 2757; 1933, 27, 309. French P. 36,990, 1929; 38,055, 1929; 39,333, 1930; addns. to 673,825, 1929; *Chem. Abs.*, 1931, 25, 965; 1932, 26, 604; 1932, 26, 2202; 1930, 24, 2757. British P. 320,375, 1928; 340,509, 1929; 341,553, 1929; *Chem. Abs.*, 1930, 24, 2757, 1931, 25, 4894.

Morgan and Coulson<sup>14</sup> studied the condensation of p-benzoquinone with 2,3-dimethylbutadiene-1,4. Their product, 2,3,6,7-tetramethyl- $\Delta^{2,6}$ -octahydroanthraquinone, isomerizes when treated with acid or alkali or when recrystallized from a high-boiling solvent. Since it could not be acetylated, it was not regarded as 2,3,6,7-tetramethyl- $\Delta^{2,6}$ -hexahydro-9,10-anthrahydroquinone,

but rather as the isomeric derivative:

By passing oxygen through an alcoholic solution of this compound, 2,3,6,7-tetramethyl anthraquinone is formed which on reduction passes into 2,3,6,7-tetramethyl anthrone; the indications are, however, that this loses water to yield 2,3,6,7,2',3',6',7'-octamethyl-10,10'-dihydro-dianthrol,

1,3-Butadienes also react with  $\alpha$ -naphthoquinones<sup>15</sup> or with the halogenated derivatives<sup>16</sup> (2-chloro- and 2,3-dichloro-1,4-naphthoquinones) to form tetrahydronaphthoquinones (or derivatives).

<sup>14</sup> G. T. Morgan and E. A. Coulson, *J.C.S.*, 1931, 2323.

<sup>15</sup> O. Diels and K. Alder, *Ann.*, 1928, 450, 110; *Chem. Abs.*, 1928, 22, 1144. *Ber.*, 1929, 62, 2365.

<sup>16</sup> French P. 37,684, 1929, addn. to 673,825, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1931, 25, 4559.

Isomerization can take place as in the case of the octahydroanthraquinones, or for the corresponding halogenated compounds, by an intermolecular elimination of halogen acid. If an oxidizing agent (nitrobenzene) is used initially in the reaction of butadiene with naphthoquinone, anthraquinone itself is obtained.<sup>17</sup>

Tetrahydroquinazarine (1,4-dihydroxy- $\Delta^4$ -tetrahydroanthraquinone) is formed from butadiene and naphthazarin (5,8-dihydroxy-1,4-naphthoquinone).<sup>18</sup>

Butadiene combines with methyl acetylenedicarboxylate in the manner of a 1,4 addition to yield a derivative which on dehydrogenation passes over into

phthalic ester.<sup>19</sup> It is of interest to note that triphenylmethyl combines both with isoprene and with dimethylbutadiene, with the addition taking place 1,4.<sup>20</sup>

The butadiene acids (sorbic<sup>21</sup> and muconic) yield, with maleic anhydride carboxylate, tetrahydrophthalic anhydrides.<sup>22</sup>

### CYCLIC BUTADIENOIDS

Cyclopentadiene and acrolein form 2,5-endomethylene- $\Delta^3$ -tetrahydrobenzaldehyde which on reduction passes into 2,5-endomethylene-hexahydrobenzaldehyde,<sup>23</sup> the semicarbazone of which on treatment with sodium acetate and acetic anhydride yields enol-norcamphenilanaldehyde acetate; this on ozonolysis and hydrolysis decomposes into norcamphor.<sup>24</sup>

Cyclopentadiene reacts vigorously and quantitatively with maleic anhydride. The compound formed under these conditions is also a bridged anhydrocyclohexene, 3,6-endomethylene- $\Delta^4$ -tetrahydrophthalic anhydride.<sup>28</sup> Citraconic anhydride yields the corresponding 1-methyl derivative

while itaconic anhydride yields a 2,5-endomethylene- $\Delta^2$ -cyclohexenylidene succinic acid,

<sup>28</sup> For the resinification of this derivative on treatment with permanganate, see E. H. Farmer and F. L. Warren, *J.C.S.*, 1929, 907.

Crude benzol contains among other substances cyclopentadiene. By treating benzol with maleic anhydride, the dienes are removed and the dibasic acid anhydride formed has been suggested as a base for resins.<sup>26</sup> The dibutyl ester of 3,6-endomethylene- $\Delta^4$ -phthalic anhydride

has been recommended as a plasticizer in nitrocellulose lacquers.<sup>27</sup>

Alder and Stein<sup>28</sup> have shown that the adduct of maleic anhydride and cyclopentadiene will further react with butadiene with the production of a bridged octahydronaphthalene derivative,

1,4-endomethylene- $\Delta^6$ -octahydro-2,3-naphthalene-2,3-dicarboxylic anhydride.

The substituted derivative of endomethylene hydrophthalic acid or 4-bromo-5-hydroxy-cis-3,6-endomethylenehexahydrophthalic acid is converted by means of 25 per cent alcoholic potassium hydroxide, followed by acetic anhydride, into the dilactone of 4,5-dihydroxy-cis-3,6-endomethylenehexahydrophthalic acid. This compound can be distilled unchanged and is not affected by hot concentrated nitric acid. Rearrangement occurs, however, with alcoholic potash into the trans-lactonic acid.<sup>29</sup>

By condensing maleic anhydride with cyclohexadiene (1,2-dihydrobenzene), a compound, 3,6-endo-ethylene- $\Delta^4$ -phthalic anhydride, is obtained whose bridge consists of two members.

An unsaturated bridge may also be formed by the condensation of cis-cyclohexadiene- $\Delta^{3,6}$ -1,2-dicarboxylic anhydride with maleic anhydride to 3,6-endodimethinehexahydro-tetracarboxylic anhydride.

Moreover, two mols of cyclopentadiene react with one mol of benzoquinone<sup>30</sup> to yield a compound which possesses two bridges, 1,4,5,8-di-endomethylene- $\Delta^{3,6}$ -octahydroanthraquinone.<sup>31</sup> Similarly with cyclohexadiene the di-endoethylene compound is obtained.<sup>32</sup>

Both cyclopentadiene and cyclohexadiene react with methyl acetylenedicarboxylic ester. The former yields dimethyl-3,6-endomethylene-3,6-dihydrophthalate; the latter forms a similar endoethylene compound.<sup>33</sup> On reduction the double bond

<sup>30</sup> A. Wassermann (*Ber.*, 1933, 66, 1392; *Chem. Abs.*, 1934, 28, 25) has measured the velocity of the reaction of quinone with cyclopentadiene to form monocyclopentadienequinone. The velocity is followed by color change inasmuch as the quinone is more highly colored than the final product. The reaction is found to be bimolecular in *n*-hexane, in carbon tetrachloride, in benzene, in ethanol and in acetic acid.

<sup>31</sup> Cf. W. Albrecht, *loc. cit.*

<sup>32</sup> O. Diels and K. Alder, *Ann.*, 1928, 460, 98; *Chem. Abs.*, 1928, 22, 1144.

between the ester groups is unaffected whereas the other bond is reduced. The reaction may be expressed

Cyclohexadiene combines with acraldehyde at 100°C. to yield 2,5-endoethylene- $\Delta^2$ -tetrahydrobenzaldehyde, the semicarbazone of which is reduced to the semicarbazone of 2,5-endoethylene-hexahydrobenzaldehyde. Subsequent treatment with acetic anhydride and sodium acetate and fission with ozone of the resulting enol-acetate yields 2,5-endoethylene-cyclohexanone.<sup>44</sup> Reduction of the 2,5-endoethylene-cyclohexanone by the Wolff-Kishner method, that is, using sodium and alcohol in the presence of semicarbazone, results in the preparation of 2,2,2-dicyclo-octane.<sup>45</sup>

Anthracene possesses diene properties to such an extent that it will react with

<sup>44</sup> O. Diels, K. Alder, E. Petersen and F. Querberitz, *Ann.*, 1930, 478, 137.

<sup>45</sup> K. Alder, G. Stein, F. von Buddenbrock, W. Freerks and S. Schneider, *Ann.*, 1934, 514, 1; *Brit. Chem. Abs. A*, 1935, 211. For the preparation of 1,2,2-dicycloheptane, see G. Komppa and S. Beckmann, *Ann.*, 1934, 512, 172; *Brit. Chem. Abs. A*, 1934, 1103.

$\alpha\beta$ -enal structures and with acetylenedicarboxylic acid to yield endo compounds.<sup>80</sup> Diels and Alder<sup>81</sup> represent anthracene as a system of conjugated double bonds

and the addition with maleic anhydride affords 9,10-endoanthracene- $\alpha,\beta$ -succinic anhydride,

which on oxidation reverts to anthraquinone.

Anthracene-acetylenedicarboxylic anhydride, similarly prepared, contains an unsaturated bridge and can further react with butadiene, 1,1,3-trimethylbutadiene and cyclopentadiene to yield complex adducts. With butadiene, the reaction may be written as follows:

Decomposition of the adduct by heat results in the formation of dihydroanthracene and phthalic anhydride. Heating the anthracene-acetylenedicarboxylic acid in nitrobenzene or phenol gives rise to carbon monoxide, carbon dioxide and a com-

<sup>80</sup> Other hydrocarbons (toluene, ethylbenzene, isopropylbenzene, tetrahydronaphthalene, diethylbenzene and 3-methylnaphthalene) react with maleic anhydride although not through a diene reaction. The reaction occurs at about 300° under pressure. Toluene and maleic anhydride yield benzyl succinic acid; ethylbenzene and maleic anhydride give rise to a product which reverts to  $\gamma$ -methyl- $\gamma$ -phenylpyrotartaric acid,

See J. Binapff, German P. 607,880, 1935, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1935, 29, 1334

<sup>81</sup> O. Deils, K. Alder and S. Beckman, *Ann.*, 1931, 485, 191; *Chem. Abs.*, 1931, 25, 3046. See G. Kalischer and H. Scheyer, German P. 539,532, 1927, addn. to 499,590, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1932, 26, 2301.

pound (m.p. 360°C.) which is stable toward potassium hydroxide, concentrated nitric acid, acetic anhydride, aniline and quinoline. This compound appears to be one in which the maleic anhydride residue is sandwiched between two anthracene molecules at the 9,10 position.<sup>39</sup>

Clar<sup>39</sup> feels that the above constitution of anthracene (p. 839) is inadequate and prefers to express the structure by the equilibrium formulas:

He comes to this conclusion partly from the observation that 9,10-endoanthracene- $\alpha\beta$ -succinic anhydride dissociates into maleic anhydride and anthracene at 250-270°C. and partly from the reaction of anthracene with p-benzoquinone in boiling xylene. In the latter instance p-benzoquinone-anthracene is formed

oxidation of which yields endo-9,10-o-phenylene-9,10-dihydro-1,4-anthraquinone

Anthracene also condenses with acrylic acid or with  $\alpha$ - or with  $\beta$ -dichloropropionic acid.<sup>40</sup>

<sup>39</sup> O. Diels and W. Friedrichsen, *Ann.*, 1934, 513, 145; *Brit. Chem. Abs. A*, 1934, 1351.

<sup>40</sup> G. Kalischer and H. Scheyer, U. S. P. 1,836,123, Dec. 15, 1931, to Winthrop Chemical Co.; *Chem. Abs.*, 1932, 26, 1130.

1,2,5,6-Dibenzanthracene reacts with maleic anhydride but the action is much more sluggish. On hydrolysis, 1,2,5,6-dibenzanthracene-9,10-endo- $\alpha\beta$ -succinic acid is obtained.<sup>41</sup>

In boiling xylene, perylene appears to form an addition compound with maleic anhydride, on cooling, however, the hydrocarbon separates unchanged. 2,3-10,11-Dibenzoperylene reacts in the following manner with maleic anhydride in boiling nitrobenzene:

Under similar conditions, neither phenanthrene nor benzanthrone react with maleic anhydride.<sup>42</sup> In the above reaction between dibenzoperylene and maleic anhydride, nitrobenzene acts as a mild oxidizing agent.

<sup>41</sup> J. W. Cook, *J.C.S.*, 1931, 3373.

<sup>42</sup> E. Clar (in part with W. Hempel), *Ber.*, 1932, 65, 846; *Brit. Chem. Abs. A*, 1932, 731.

Tetraphenylcyclopentadienone has been used with maleic acid to build highly arylated systems. 3,6-Endocarbonyl-3,4,5,6-tetraphenyl- $\Delta^4$ -dihydrophthalic acid anhydride is obtained, which on decarboxylation yields 1,2,3,4-tetraphenyl benzene.<sup>48</sup> The derivative formed by the action of maleic anhydride on tetraphenylcyclopentadienone namely, 3,6-endocarbonyl-3,4,5,6-tetraphenyl-1,2-dihydrophthalic anhydride loses carbon monoxide on heating to yield 3,4,5,6-tetraphenyl-1,2-dihydrophthalic anhydride which may be dehydrogenated by sulphur.<sup>48</sup>

Depending on the temperature at which the addition of maleic anhydride takes place, different compounds are formed. In boiling benzene, tetraphenylcyclopentadienone and maleic anhydride yield the endo derivative; in chlorobenzene, the hydrated phthalic acid is obtained; whereas in nitrobenzene, tetraphenylphthalic anhydride results. The accumulation of phenyl groups hinders the reactivity of tetraphenylphthalic anhydride; it does not dissolve in aqueous ammonium hydroxide and is not esterified with ethanol. When esters are prepared, that is, by the action of tetraphenylcyclopentadienone on the dialkyl ester of acetylene dicarboxylic acid, the esters can not be hydrolyzed.<sup>48</sup>

Two mols of 3,4-diphenylcyclopentadienone undergo auto-reaction, yielding a diketone; the latter is also formed by dehydration of anhydroacetonebenzil (4-hydroxy-3,4-diphenyl- $\Delta^2$ -cyclopentenone).<sup>48</sup> The diketone splits out carbon monoxide when heated, forming a ketone as shown in the equation on page 843. Further heating results in rearrangement to 2,3,5,6-tetraphenylhydrindone.

## TERPENOIDS

Myrcene, 6-methyl-2-vinyl-1,5-heptadiene, an acyclic terpene, possesses a conjugate linkage and will react with either crotonic aldehyde or with maleic anhydride. With the aldehyde, myrcene yields a partially hydrogenated benzaldehyde,

6-methyl-3-isohexenyl- $\Delta^4$ -tetrahydrobenzaldehyde. With maleic anhydride, 4-isohexenyl-cis- $\Delta^4$ -tetrahydrophthalic anhydride can be synthesized.<sup>47</sup>

A cyclic terpenoid under the same conditions gives rise to a branched bridge. For example, with  $\alpha$ -phellandrene and acrolein, 2,5-endo-isoamylene-1,2,5,6-tetrahydro-1-benzaldehyde is obtained.<sup>48</sup>

<sup>47</sup> The melting point of the corresponding acid is 122-3°C. B. A. Arbusov and U. S. Abramov (*Ber.*, 1934, 67, 1942; *Chem. Abs.*, 1935, 29, 1384) dehydrated linalool,

and condensed the dehydrated product (which should be myrcene) with maleic anhydride and obtained the acid which melted much lower (111-113.5°C.). Attempts to isomerise the acid with hydrogen bromide into dimethyloctahydronaphthalene-6,7-dicarboxylic acid were unsuccessful; an uncrystallizable oil resulted.

<sup>48</sup> O. Diels, K. Alder, W. Lübbert, E. Naujoks, F. Querberits, K. Röhl and H. Segeberg, *Ann.*, 1929, 470, 62; *Chem. Abs.*, 1929, 23, 3692. B. A. Arbusov (*Ber.*, 1934, 67, 563; *Chem. Abs.*, 1934, 28, 4402) isomerised  $\alpha$ -pinene to an aliphatic terpene by passing the vapors of the pinene over reduced copper or

The reaction product of  $\alpha$ -terpinene and maleic anhydride has found use in the production of safety glass,<sup>49</sup> whereas the resin obtained by heating  $\alpha$ -terpinene, maleic anhydride and abietic acid at 125-250°C. has been suggested for varnishes.<sup>50</sup>

$\alpha$ -Terpinene may be derived from pinene, dipentene,  $\alpha$ -terpineol and terpenehydrate by means of sulphuric acid. By gradually treating 2 liters of pinene with 70 cc. of sulphuric acid, rearrangement takes place. Neutralization with alkali together with steam distillation and fractionation yields  $\alpha$ -terpinene.

When 480 parts of  $\alpha$ -terpinene are heated with 294 parts of maleic anhydride at 150-200°C. for 5 hours and the reaction mixture is subjected to vacuum évaporation, a soft amorphous solid is obtained.<sup>51</sup> Esterification of 1 mol of the resulting terpinene-maleic anhydride with 4 mols of butyl alcohol at 117°C. for 4 hours yields the monobutyl terpinene-maleate. If sulphuric acid is added, dibutyl terpinene-maleate results. Esterification with glycol yields a pale yellow, resinous solid soluble in acetone, toluene and butyl acetate whereas esterification with glycerol gives rise to a hard and brittle resin.<sup>52</sup> Terpinene-maleic anhydride can

through tubes filled with fragments of Suprax glass at 340°. A synthesis was undertaken to prove the structure of the isomeric derivative to be alloöcimene (*ibid.*, 569). Meanwhile F. G. Fischer and K. Löwenberg (*Ber.*, 1933, 66, 669; *Chem. Abs.*, 1933, 27, 3446) had synthesized alloöcimene from 2-methyl-2,4-heptadien-6-one and  $\alpha$ -bromoethyl propionate by means of the Reformatsky reaction and definitely deduced that alloöcimene was 2,6-dimethyl-2,4,6-octatriene [(CH<sub>3</sub>)<sub>2</sub>C=CH-CH=CH-C(CH<sub>3</sub>)<sub>2</sub>=CH-CH<sub>3</sub>]. B. A. Arbuzov (*Ber.*, 1934, 67, 1946; *Chem. Abs.*, 1935, 29, 1407) then determined that the maleic anhydride addition compound of alloöcimene was identical with the maleic anhydride addition product of isomerized  $\alpha$ -pinene.

<sup>49</sup> G. H. Peters, U. S. P. 1,832,298, Oct. 11, 1932, to Hercules Powder Co.; *Chem. Abs.*, 1933, 27, 824.

<sup>50</sup> E. G. Peterson, U. S. P. 1,978,598, Oct. 30, 1934, to Hercules Powder Co.; *Chem. Abs.*, 1935, 29, 254.

<sup>51</sup> E. G. Peterson and E. R. Littmann, U. S. P. 1,993,025, Mar. 5, 1935, to Hercules Powder Co.; *Chem. Abs.*, 1935, 29, 2623.

<sup>52</sup> E. R. Littmann, U. S. P. 1,993,026, Mar. 5, 1935, to Hercules Powder Co.; *Chem. Abs.*, 1935, 29, 2623. For further discussion of this type of resin see Chapters 41-49.

be reacted with glycerol in the presence of rosin or with linseed or tung oil acids.<sup>53</sup> The terpene-maleate may be formed by heating at 200°C. 165 parts of abietic acid, 98 parts of maleic anhydride and 85 parts of  $\alpha$ -terpinene. The derivative so prepared may be further esterified with methanol in the presence of sulphuric acid,<sup>54</sup> or with glycerol in the presence of stearic acid.<sup>55</sup>

Terpenes containing no conjugated double bonds react with maleic anhydride or with fumaric acid which rearranges into maleic anhydride when heated. The terpenes which will undergo this reaction include  $\alpha$ -pinene,  $\beta$ -pinene, dipentene (and its isomers d- and l-limonene) and terpinolene.

When 400 parts of  $\alpha$ -pinene and 100 parts of maleic anhydride are heated in an autoclave at 170-175°C. under 5-10 pounds pressure for 3 hours, a soft yellow-colored acidic resin is obtained<sup>56</sup> which may be esterified with glycerol monomethyl ether,<sup>57</sup> glycerol, polyglycerol or glycol.<sup>58</sup> Pinene-maleic anhydride on saponification does not yield an alcohol, indicating that a carbon-carbon union has been formed. p-Toluenesulphonic acid assists the union of maleic anhydride and pinene<sup>59</sup> but at the same time causes rearrangement of the terpene.<sup>60</sup> By heating 100 parts of  $\alpha$ -pinene, 165 parts of abietic acid and 98 parts of maleic anhydride, a resin is formed having an acid number of 250, the acidity of which may be reduced by esterification with glycerol.<sup>61</sup>

saturated phthalic anhydride derivatives react with phenyl azide<sup>66</sup> to produce triazole derivatives which find use as intermediates for drugs.

With 2,5-dimethylfuran, 3,6-endo-3,6-dimethyl- $\Delta^4$ -tetrahydrophthalic anhydride is formed.<sup>67</sup> Rinkes<sup>68</sup> prepared 3-methylfuran and this likewise reacted with maleic anhydride to give 3,6-endo-4-methyl- $\Delta^4$ -tetrahydrophthalic anhydride. 2-Methylfuran yielded 3,6-endo-3-methyl- $\Delta^4$ -tetrahydrophthalic anhydride.

In boiling toluene, methyl coumalate also forms an adduct with maleic anhydride, giving a 30 per cent yield of 3,6-endo-carboxy-4-methyl-carboxylate- $\Delta^4$ -tetrahydrophthalic anhydride.

In boiling xylene, however, a 30 per cent yield of 3,6-endo-succinic-anhydride-4-methyl-carboxylate- $\Delta^4$ -tetrahydrophthalic anhydride is obtained.<sup>69</sup>

#### HETEROCYCLIC NITROGEN COMPOUNDS

Although pyrrole is a diene system, it behaves differently with maleic anhydride than its oxygen analogue, furan. Diels and Alder<sup>70</sup> found that maleic anhydride and pyrrole react at room temperature to give only a small quantity of pyrrole-dipropionic acid; dilevulic acid (4,7-decandion-1,10-dioic acid), however, could be isolated in quantity. The mechanism of the reaction was studied with 2-methylpyrrole which yields 2-methylpyrrole-5-succinic acid. This acid readily loses carbon dioxide to form 2-methylpyrrole-5-propionic acid.

<sup>66</sup> K. Alder and G. Stein, German P. 557,238, 1931, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1933, 27, 1003. K. Alder, G. Stein and W. Friedrichsen (*Ann.*, 1933, 501, 1; *Chem. Abs.*, 1933, 27, 2139) discuss in some detail the conditions necessary for the addition of phenyl azide to an unsaturated system.

<sup>67</sup> O. Diels and K. Alder, *Ber.*, 1929, 62, 554; *Brit. Chem. Abs. A.*, 1929, 570.

<sup>68</sup> J. Rinkes, *Rec. trav. chim.*, 1931, 50, 1127; *Chem. Abs.*, 1932, 26, 1279. For another synthesis of 3-methylfuran, see T. Reichstein and H. Zschokke, *Helv. Chim. Acta*, 1931, 14, 1270; *Brit. Chem. Abs. A.*, 1932, 166.

<sup>69</sup> O. Diels, K. Alder and K. Müller, *Ann.*, 1931, 490, 257; *Brit. Chem. Abs. A.*, 1931, 1427.

<sup>70</sup> O. Diels and K. Alder, with D. Winter, *Ann.*, 1931, 486, 211; *Brit. Chem. Abs. A.*, 1931, 849. Toward triphenylmethyl, however, pyrrole behaves as a diene. See J. B. Conant and B. F. Chow, *J.A.C.S.*, 1933, 55, 3475.

The assumption naturally follows that the formation of pyrrole-2,5-dipropionic acid arises by decarboxylation of an intermediate tetracarboxylic acid (analogous to 2-methylpyrrole-5-succinic acid) and the dilevulic acid, by the hydrolysis of pyrrole-2,5-dipropionic acid.

The 1-methylpyrrole-2,5-dipropionic acid is more resistant to hydrolysis, consequently the proportion of dilevulic acid is smaller.

2,4-Dimethylpyrrole and citraconic anhydride in non-aqueous solvents react to yield a compound of the structure,

2-Methylpyrrole and methyl acetylenedicarboxylate combine additively at room temperature to yield stereoisomeric dimethyl esters which are cis- and trans-modifications inasmuch as they yield the same 2-methylpyrrole-succinic acid on catalytic reduction,

2,3-Dimethyl- and 2,3,4-trimethylpyrrole behave similarly to 2-methylpyrrole. 1-Methylpyrrole and acetylenedicarboxylic acid form 1-methylpyrrole-2-maleic acid. 2,4-Dimethylpyrrole, however, gives rise to a compound having two nitro-

gen components. N-Methylindole behaves in the same manner. Methyl acetylenedicarboxylate, on the other hand, with 1-methylpyrrole reacts to give an indole of the structure<sup>71</sup>

Maleic anhydride and 2-methylindole in benzene solution yield  $\alpha$ -2-methylindolyl-3-succinic anhydride and the compound,

With 1,2-dimethylindole and maleic anhydride similar compounds are obtained.<sup>72</sup>

Methyl acetylenedicarboxylate and 4-methylglyoxaline in ether form methyl  $\alpha$ -4-methyl-2-glyoxalanyl-maleate. The 5-methylglyoxaline behaves in an analogous manner. Two mols of methyl acetylenedicarboxylate, however, combine with 1,2-dimethylglyoxaline in ethereal solution at room temperature to give an alizarin-red colored methyl 1,8-dimethyl-1,8-dihydropyriminazole-4,5,6,7-tetracarboxylate. This pyriminazole derivative, on treatment with bromine in methyl alcohol, is converted to methyl 2-methylpyridine-3,4,5,6-tetracarboxylate; with acetic acid, a loss of methylamine takes place and the resulting compound is an indolizine ester.

<sup>72</sup> O. Diels, K. Alder, U. Lübbert, H. Winckler, E. Heinrich, W. Lück and W. Eckhardt, *Ann.*, 1931, 490, 277; *Brit. Chem. Abs. A*, 1931, 1428.

The addition principle underlying the formation of the 1,8-dihydropyriminazole derivative is the addition of two mols of acetylenedicarboxylic ester to the  $=C=N-$  double bond.

On the other hand,  $\alpha\beta$ -unsaturated nitriles react with dienes (cyclopentadiene, cyclohexadienes and butadienes) to form compounds retaining the nitrile group.<sup>75</sup> Thus crotonic acid nitrile adds to cyclopentadiene to yield 3-6-endomethylene- $\Delta^4$ -tetrahydro-1-methyl-2-cyanobenzene.

The principle<sup>76</sup> of addition to the  $=C=N-$  double bond is shown in the case of pyridine, quinoline and isoquinoline.<sup>77</sup> Pyridine and methyl acetylenedicarboxylate in ethereal solution yield tetramethyl quinolizine-1,2,3,4-tetracarboxylate which has been applied to a synthesis of conine, norlupinane and  $\psi$ -lupinine.<sup>78</sup> In addition to the quinolizine derivative, however, there are two other compounds formed when pyridine reacts with methyl acetylenedicarboxylate. The yellow quinolizine compound will pass over into a red modification; it is also formed initially in the reaction in very small amounts. There is a second red variety which is isomeric with the yellow quinolizine compound and which reverts into the yellow form on recrystallization. Diels, Alder<sup>77</sup> and collaborators have recently studied the constitution of these derivatives and assign the name tetramethyl quinolizine-1,2,3,4-tetracarboxylate to the yellow substance.

The red modification, also known as the "Kashimoto-body," is considered to be:

<sup>75</sup> British P. 341,047, 1928, to I. G. Farbenind., A.-G.; *Chem. Abs.*, 1931, 25, 4891.

<sup>76</sup> O. Diels, K. Alder, H. Winckler and E. Petersen, *Ann.* 1932, 498, 1; *Brit. Chem. Abs. A*, 1932, 1144.

<sup>77</sup> O. Diels, K. Alder, T. Kashimoto, W. Friedrichsen, W. Eckhardt and H. Klare, *Ann.*, 1932, 498, 16; *Chem. Abs.*, 1932, 26, 5951.

<sup>78</sup> O. Diels, K. Alder, W. Friedrichsen, H. Klare, H. Winckler and Schrum, *Ann.*, 1933, 505, 103; *Brit. Chem. Abs. A*, 1933, 1058.

<sup>77</sup> O. Diels, K. Alder, W. Friedrichsen, E. Petersen, Brodersen and Kech, *Ann.*, 1934, 510, 87; *Chem. Abs.*, 1934, 28, 5481.

The isomeric red derivative known as the labile isomer is written as a pseudo-pyridinium structure,

This isomer is considered to be the intermediate in the quinolizine formation. The structure of this compound was obtained by treatment with diazomethane to form an adduct and splitting the resulting compound with hydrochloric acid into pyridine hydrochloride, dimethyl pyrazol-1,2,-dicarboxylate and dimethyl acetylenedicarboxylate.

and

In a similar manner, quinoline and methyl acetylenedicarboxylate in benzene give a bright yellow addition product which is converted into a stable red isomer either by heating or by the action of concentrated sulphuric or hydrobromic acid. The quinoline derivatives behave in much the same manner as the pyridine compounds described above.

Diels and Meyer<sup>12</sup> have continued the study of compounds formed by reaction of pyridine and acetylenedicarboxylic acid esters. In methyl alcohol solution at 0°C. a colorless derivative is obtained which is known as the "white adduct" and which has been shown to be 1-( $\alpha$ -methoxy- $\alpha$ -carbmethoxy)-2,3-carbmethoxyindolizine. The "white adduct" on oxidation with hydrogen peroxide in acetic acid yields  $\alpha$ -picolinic acid; with alcoholic potash, hydrolysis occurs with the formation of 1-( $\alpha$ -methoxy- $\alpha$ -carboxy)-indolizine-2,3-carboxylic acid which is converted by boiling acetic anhydride into 1-( $\alpha$ -methoxy- $\alpha$ -acetyl)-indolizine-2,3-dicarboxylic anhydride.

<sup>12</sup> O. Diels and K. Meyer, *Ann.*, 1934, 513, 139; *Chem. Abs.*, 1935, 29, 1419.

Reduction of 1-( $\alpha$ -methoxy- $\alpha$ -carboxy)-indolizine-2,3-dicarboxylic acid yields a resin which is converted with acetic anhydride into the tetrahydro derivative of 1-( $\alpha$ -methoxy- $\alpha$ -acetyl)-indolizine-2,3-dicarboxylic anhydride.

The mechanism of the addition of acetylenedicarboxylic acid esters to pyridine is not too well understood but the reaction has been explained in the following manner. Two molecules of the ester react to form an unsaturated chain

In ethereal solution the chain attaches itself to the nitrogen of the pyridine with the formation of quinolizine compounds. In methyl alcohol solution, however, 2 mols of alcohol could attach themselves to the unsaturated acetylene ester chain.

On fission 2 mols of methoxyfumaric ester should result. Credence to this hypothesis is substantiated by the isolation of methyl fumarate and methyl methoxyfumarate in the mother liquors in the preparation of the "white adduct." The addition of one molecule of methyl alcohol to the unsaturated ester chain would yield the following

On the basis of the same type of addition as was noted in the formation of the pseudo-pyridinium structure, the reaction will take place as follows:

Diels and Reese<sup>79</sup> indicate that hydrazobenzene also forms an adduct with methyl acetylenedicarboxylate whose structure may be expressed as

This compound may undergo a variety of reactions: by intramolecular loss of methyl alcohol, methyl 1,2-diphenylpyrazol-5-one-3-carboxylate is formed:

by loss of aniline, methyl- $\alpha,\beta$ -indole carboxylate,

and by loss of methyl alcohol and rearrangement, methyl 2-hydroxy-3-anilidoquinoline-4-carboxylate.

#### HEXATRIENES AND HIGHER POLYENES

The hexatrienoids yield cyclohexene derivatives. Both the *cis* and the *trans* form of 1,3,5-hexatriene with maleic anhydride give rise to the same ethylidene cyclohexene derivative.<sup>80</sup>

<sup>79</sup> O. Diels and J. Reese, *Ann*, 1934, 511, 168; *Chem Abs*, 1934, 28, 5453

<sup>80</sup> E. H. Farmer and F. L. Warren, *J.C.S.*, 1929, 901.

1,8-Diphenyl-1,3,5,7-octatetraene unites with the same reagent to give the following:

The reaction in this instance is probably dominated by the strong reactivity of the terminal methine groups. This seems to be true in the case of the higher hydrocarbons of the structure

1,10-Diphenyl-1,3,5,7,9-decapentaene reacts with either 2 or 3 mols of maleic anhydride. When 2 mols of the anhydride react, addition appears to take place in positions 1,4 and 7,10.<sup>22</sup>

By a so-called "additive heteropolymerization" maleic anhydride reacts with stilbene in boiling xylene solution to yield a compound of high molecular weight which is insoluble in most organic solvents and only colloiddally soluble with preliminary swelling in camphor. On dry distillation stilbene is regenerated. Wagner-Jauregg considers the structure to be according to a definite plan:

Amylene and styrene heated with maleic anhydride give viscous gummy masses.

The  $\text{C}=\text{N}$  union seems also capable of additive heteropolymerization, for with benzal- or cinnamal-azine, maleic anhydride reacts to form brown or yellow amorphous masses.<sup>23</sup> Asymmetrical diphenylethylene reacts with 2 mols of maleic anhydride to yield a crystalline derivative but when heated to  $330^\circ\text{C}$ . reverts partly to maleic anhydride and to unidentified resinous material. Wagner-Jauregg<sup>24</sup> considers this addition to be of the nature of the addition of maleic anhydride to pyrrole which does not involve a 1,4 addition. The structure would be, presumably:

<sup>22</sup> R. Kuhn and T. Wagner-Jauregg, *Ber.*, 1930, 63, 2662; *Brit. Chem. Abs. A*, 1930, 1580.

<sup>23</sup> T. Wagner-Jauregg, *Ber.*, 1930, 63, 3213.

<sup>24</sup> T. Wagner-Jauregg, *Ann.*, 1931, 491, 1; *Chem. Abs.*, 1932, 26, 982.

Alder,<sup>24</sup> however, considers that one of the double bonds of the benzene ring acts as a conjugated system with the bond of the side chain. The first maleic anhydride acts on the system 1,4,

and the second maleic anhydride 1,4 on the second conjugate system in the benzene ring:

Certain types of reactions take place between monolefins and compounds containing the  $\alpha\beta$ -enal grouping. The structure of these derivatives has not been determined but they may be mentioned at this point. Olefins can be condensed with maleic acid, crotonic acid, acrylic acid, acrylic aldehyde or quinone. "Amylene succinic acid" has been prepared by heating amylene for 2 hours at 180°C. with 20 per cent by weight of maleic anhydride. The olefin aldehydes or carboxylic acids are useful in resin manufacture.<sup>25</sup>

Daimler<sup>26</sup> heated maleic acid with glycols such as 1,3-butylene glycol which are capable of splitting off water with the formation of unsaturated compounds. With 1,3-butylene glycol, the product is a syrupy liquid soluble in ammonium hydroxide. Maleic anhydride also reacts with castor oil and when this is combined with the product from maleic acid and 1,3-butylene glycol, an adhesive composition is obtained that is useful in safety glass manufacture.<sup>27</sup>

## ROSIN-MALEIC ANHYDRIDE ADDUCT

The diene synthesis, particularly the reaction with maleic anhydride, has thrown new light on the structure of abietic acid. The presence of two double bonds in abietic acid, but not their position is shown by hydrogenation. A dihydro-derivative is readily obtained but the tetrahydro with much more difficulty. Oxidation with perbenzoic acid likewise shows two double bonds.

Methyl abietate and maleic anhydride at 160°C. yield an additive compound of the formula  $C_{28}H_{44}O_5$  which on hydrolysis passes over into the anhydride carboxylic acid  $C_{28}H_{42}O_5$  (m.p. 227-8°C.). This same compound is obtained from American colophony by direct treatment with maleic anhydride. The fact that abietic acid and maleic anhydride react indicates that a diene system probably exists and the formula of abietic acid may be written<sup>28</sup> provisionally as:

Arbuzov<sup>29</sup> prepared the same compound of abietic acid and maleic anhydride,  $C_{28}H_{42}O_5$ , (m.p. 227°C.).

The adduct when heated with selenium to 300°C. yielded retene, which may also be obtained from abietic acid and heat directly. The natural assumption is that the maleic anhydride dissociates during the reaction. That this is not wholly the explanation is shown by the fact that abietic-maleic anhydride dissociates at 385-400°C. whereas retene is formed at 300°C.

Rosin reacts with maleic anhydride on heating. Other anhydrides (aconitic

<sup>28</sup> L. Rusicka, P. J. Ankersmit and B. Frank, *Helv. Chim. Acta*, 1932, 15, 1239; *Brit. Chem. Abs. A*, 1932, 1254. See also Chapter 37.

<sup>29</sup> B. Arbuzov, *J. Gen. Chem. U. S. S. R.*, 1932, 2, 806; *Chem. Abs.*, 1933, 27, 2683.

and citric) will also react. The resulting acids may be esterified with alcohols or with glycerol to yield resins.<sup>90</sup> The process may be applied to rosin, ester gums derived from rosin, phenol-formaldehyde resins modified with rosin, or alkyls modified with rosin. Other resins, such as dammar and gum mastic, may also be used.<sup>91</sup>

The quantity of unsaturated acid added varies from 5-35 per cent of the weight of unsaturated resin. Thus, 35 parts of maleic anhydride are introduced at 150°C. into 100 parts of American wood rosin. After 1.5 hours the product no longer gives the Storch-Morawski test for colophony, but forms a brown resin softening about 25°C. above the softening point of the initial rosin. By the use of 150 parts of colophony, a product is obtained which may be esterified with glycerol, yielding a resin softening at a higher temperature than rosin glycerol ester.

The condensation with the unsaturated acid may be effected in solution: 100 parts of colophony and 30 parts of maleic anhydride yield, on refluxing for 4.5 hours in o-dichlorobenzene a resin softening above 100°C. and having an iodine value of 63. On heating the products obtained according to these two methods at 250-350°C., either with or without addition of 5 per cent of zinc chloride, resins of low acid number are produced. All these resinous substances are soluble in alkali, and the solutions yield the corresponding heavy-metal resins on the addition of metallic salts. The method is particularly adaptable to the preparation of the corresponding lead carboxylate. If 33 parts of trihydroxystearic acid are heated *in vacuo* to 200°C. with 40 parts of the rosin-maleic adduct, a resin is produced having properties resembling those of shellac.

The products formed by condensation of maleic anhydride with a glycerol or sorbitol ester of rosin are not soluble in alkali, but dissolve in benzene. For the production of a varnish, an equal weight of linseed oil may be added to a resin formed by heating 100 parts of colophony with 35 parts of maleic anhydride at 150°C., the whole being heated for 5 hours at 250°C. Decrease in the proportion of maleic anhydride to 25 per cent by weight results in formation of a resin of higher softening point. According to Robertson,<sup>92</sup> linseed and bodied oils (slow drying) and the glycerol-maleic acid-rosin types of resin give good colors in paints formulated with titanium pigments.

The rosin-maleic-glycerides have been found to possess properties rendering them adaptable to the production of light-colored high-grade varnishes.<sup>93a</sup> One particular rosin-maleic-glyceride has an acid number below 28, and is soluble in hydrocarbon solvents, turpentine and drying oils, but insoluble in the lower aliphatic alcohols. As a baking enamel, the resin may be mixed with one and a half parts of linseed oil and heated as high as 90°C.; as an air-drying varnish, one part of resin may be used with three or four parts of drying oil. The pale color and light-fastness of the resin render it useful for light-tinted enamels or varnishes. Such varnishes have good insulating properties. Maleic rosin glyceride is compatible with nitrocellulose, although its greater hardness necessitates the use of larger amounts of plasticizers.

#### THE DIENE SYNTHESIS AND THE STRUCTURE OF DRYING OILS

Fokin<sup>93</sup> was apparently the first to suggest that conjugated double bonds existed in the tung-oil molecule. Recent researches based on the ozonolysis<sup>94</sup> of the com-

pound have borne out this contention and the formula assigned to eleostearic acid is

Two reactions take place on halogenation. The first trace of halogen causes an isomeric change, the  $\alpha$ -eleostearic acid goes over into the  $\beta$ -variety inasmuch as the same crystalline hexabromide is obtained with either the  $\alpha$ - or  $\beta$ -form by halogenation in carbon tetrachloride in the presence of ultraviolet light. Debromination results in the regeneration of the  $\beta$ -eleostearic acid. Four atoms of bromine are taken up readily whereas the hexabromoeleostearic acid is formed slowly and in a poor yield.\*

Now, inasmuch as the eleostearic acids contain a system of double bonds, they should act as dienes with maleic anhydride to form a substituted, partially hydrogenated phthalic anhydride. This was found to be the case. Morrell and Samuels\*\* investigated this reaction between maleic anhydride and the  $\alpha$ - and  $\beta$ -eleostearic acids of tung oil. Both of these acids gave crystalline derivatives, the structures of which could be determined by oxidation with potassium permanganate and are

The structural formulas assigned above receive added support from surface-potential measurements. On dilute acid solution both the  $\alpha$ - and  $\beta$ -form spread to a unimolecular film with a limiting area of about 125 square Å per molecule. This is taken to mean that the molecules are flat on the surface and not end-on, as is ordinarily the case. The films of both the  $\alpha$ - and  $\beta$ -form behave similarly on compression down to an area of 100 square Å, whereupon for the  $\alpha$ -derivative the surface potential of the film falls from +280 to +80 m.v. on compression from 80-30 square Å; for the  $\beta$ -derivative under the same compression, the potential rises from +260 to +285 m.v.

This difference may be explained on the basis of alternating polarity. The magnitude of the polarity with respect to the maleic anhydride residue in each com-

\* J. Van Loon, *Rev. trav. chim.*, 1931, 50, 32; *Chem. Abs.*, 1931, 25, 2689.

\*\* R. S. Morrell and H. Samuels, *J.C.S.*, 1932, 2351. R. S. Morrell, S. Marks and H. Samuels, *J.S.C.I.*, 1933, 52, 130T.

pound will be the same but opposite in direction along the chain. On compression of the film from the state where the molecules are flat in the surface to the point where only the terminal group is in the surface, it follows that the 9,10-double bond (from the carboxyl) in the  $\alpha$ -compound is  $\pi$  when it is moved from the surface and when tending toward the vertical. This will oppose the  $\pm$  vertical component of the carboxyl group and tend to decrease the total vertical component of the electric moment per molecule much more than in the  $\beta$ -derivative where the electric moment of the 5,6-double bond (from the methyl group) is in the same sense as that of the carboxyl group on compression.

$\beta$ -Eleostearin-maleic anhydride differs from the  $\alpha$ -modification in that the solution can be stored at temperatures of 80-100°C. to give films which resist the action of cold alcohol, benzene and xylene. The  $\alpha$ -eleostearin films do not dry even after 8 hours heating and do not resist the action of benzene. This thermohardening property of the  $\beta$ -compound appears to be due to the oxidation of the double bond on the end remote from the glyceryl group. In the case of the  $\alpha$ -compound, steric hindrance is offered as a possible explanation for the retardation of oxidation.<sup>97</sup>

The  $\beta$ -eleostearin adduct with maleic anhydride is a pale yellow viscous mass, very readily soluble in acetone, alcohol, ether, benzene, turpentine and glacial acetic but only slightly soluble in 40-60°C. petroleum ether. When freshly prepared, it is miscible with linseed oil. Analytical figures showed the compound to be a triglyceryl ester of the formula  $C_{57}H_{102}(C_{22}H_{34}O_4)_3$ . A benzene solution of the product stored at 90-100°C. in 90 minutes to a hard colorless film which was elastic, non-webbing, non-frosting and non-blooming. The film may be dried at ordinary temperatures by use of cobalt linoleates or manganese resins. Neutralizing the acidity by further esterification or by the addition of lime increases the viscosity of the varnish.<sup>98</sup>

Adam and Morrell<sup>99</sup> have developed a method of measuring the water-attractive power of varnishes by determining the angle of contact between the film and water. This angle is determined to within 5° by tilting a flat plate until the water surface remains undistorted. With practically all of the varnishes, it was found that "blooming" accompanies a contact angle of less than 60°. If the angle is greater than 80°, the varnish does not bloom. The exceptions were those instances where the films dried slowly such as leaded drying oil. Stoving, which destroys blooming, increases the contact angle. In non-blooming varnishes which have angles from 80-100°, it appears as if all the oxygenated portions of the linoxyn molecules were covered by hydrocarbon residues through orientation.

The film-contact angles of some of the air-dried and some of the  $\beta$ -eleostearic-maleic anhydride films were found to bloom and have low contact angles whereas the very slow drying  $\alpha$ -films have high contact angles and show no bloom. Cobalt, manganese and lead-resinate driers have no apparent effect on the angle of contact or on the blooming of the films. Esterification of the  $\beta$ -derivative with either glycerol or glycol raises the contact angle and thereby diminishes the water-attractive power. It appears as if the greater exposure of the double bond in the  $\beta$ -compound might be responsible for the more rapid drying. Indications point to the fact that in the dried film the molecules tend to stand more or less perpendicular to the surface with the carboxyl end buried in the interior.<sup>100</sup>

At high temperatures (the so-called "stand-oil formation"), it has been sug-

<sup>97</sup> A. H. Hughes (*J.C.S.*, 1933, 338), in a study of the surface films of  $\alpha$ - and of  $\beta$ -eleostearic acid-maleic anhydride, found that both acids undergo autoxidation in the unimolecular film but that this is completely inhibited by 0.12 per cent of quinol in the substrate.

<sup>98</sup> R. S. Morrell, S. Marks, and H. Samuels, *British P.* 407,987, 1932; *Brit. Chem. Abs. B*, 1934, 511.

<sup>99</sup> N. K. Adam and R. S. Morrell, *J.S.C.I.*, 1934, 53, 255T.

<sup>100</sup> N. K. Adam and R. S. Morrell, *J.S.C.I.*, 1934, 53, 360T.

gested that the conjugated system of eleostearic acid may undergo a reaction analogous to the diene synthesis with the formation of high-molecular glycerides. The reaction would probably be pictured as:

It has also been speculated that linseed oil, at high temperatures, through isomerization may pass over into a diene system to undergo a similar intermolecular change. The transformation of linseed oil, however, is more complicated due to the fact that unpolymerized linseed oil also undergoes re-esterification.<sup>101</sup>

Jordan<sup>102</sup> is also of the opinion that in the first stages of polymerization of eleostearic acid there is a loss of one double linkage for each molecule of acid. He also proposed a **T** formula for the glycerides in place of the more usual **E** representation.<sup>103</sup> Using the **T** form it can be shown that combination can take place only by union of separate molecules.<sup>104</sup>

In a study of the eleostearic acids, Rossman<sup>105</sup> maintains that below 300°C. polymerization does not occur beyond the dimeric stage. Cyclomonoeleostearic acid (b.p. 200°C. at 4 mm.) is formed in variable amounts by heating  $\alpha$ - and  $\beta$ -eleostearic acids. Rossman believes it to be 2-butyl- $\Delta^{3,5}$ -cyclohexadienyl octoic acid

A cyclodieleostearic acid is reported to have been separated from tung oil that had been gelled and further heated at 290°C. for 0.5 hour.

In the heat-polymerization of the highly unsaturated fatty acids isolated from Japanese sardine oil, the following factors were noted: the iodine value falls, the specific gravity and refractive index rise, the specific viscosity rises rapidly. The acid and saponification values decrease, while the ester value increases. Extraction of the syrupy polymerization products with light petroleum yielded resinous substances. Toyama and Tsuchiya<sup>106</sup> consider that, in the first stages of polymerization, intramolecular change such as ring formation preponderates over extra-molecular polymerization.

Van Loon<sup>107</sup> has studied oiticica oil from the *Couepa grandiflora* or *Licania rigida* of Brazil; this oil contains "couepinic acid," an acid which is a geometrical isomeride of  $\alpha$ - and  $\beta$ -eleostearic acids. Po-yoak oil (from *Parnarium Sherbroesne*) is closely related to oiticica oil and may find use as a tung oil substitute.<sup>108</sup> The  $\beta$ -couepin of this oil reacts with maleic anhydride to yield a viscous syrup; it has not been reported to have given a fully thermohardening resin.<sup>109</sup>

## Chapter 4I

### Polybasic Acid-Polyhydric Alcohol Resins. Alkyd Resins. Theoretical

The esterification of polybasic acids by polyhydric alcohols leads almost invariably to the formation of condensation products of high molecular weight. It is, indeed, only in a few cases—such as the esterification of ethylene glycol with carbonic or oxalic acid derivatives—that the simple monomeric ester is formed in other than a very small yield. This simple reaction may be represented as follows:

More usually, as was first noted by von Bemmelen<sup>1</sup> in the esterification of succinic acid,  $\text{HOOC—CH}_2\text{CH}_2\text{—COOH}$ , with glycerol,  $\text{HOCH}_2\text{—CHOH—CH}_2\text{OH}$ , the product is a vitreous, resin-like body.

The utilization of these polymeric compounds or resins was tardy, partly owing to their high cost but more particularly to a lack of recognition of their qualities and variety of uses. In recent years, however, phthalic anhydride, the anhydride of the simplest aromatic dibasic acid, has become a readily accessible industrial product used in the manufacture of dyestuffs. When this acid is combined with glycerol, a by-product of the soap industry, the so-called alkyd resins are obtained and these have acquired considerable industrial importance.

**Phthalic Glyceride.** Whenever an organic acid reacts with an alcohol the product is an ester. The reaction between phthalic anhydride (or acid) and glycerol is no exception to this rule, but the ester formed is of a complex nature, having a high molecular weight and resinous properties and thus differing greatly from ordinary esters. As is known, polybasic acids, reacting with monohydric alcohols, form simple esters, (diethyl phthalate from ethyl alcohol and phthalic anhydride). Moreover, polyhydric alcohol esters of monobasic acids are without complexity (triacetin and vegetable oils). The high degree of molecular complexity of the resinous esters formed when both components are poly-functional<sup>2</sup> can be explained if one considers the various ways in which combination is possible.

When phthalic anhydride and glycerol are heated the first product may be assumed to be the phthalic acid monoglyceride:

That this is not the final product is easily understood when it is noted that this compound is simultaneously both an acid and an alcohol. Further reaction is there-

<sup>1</sup> J. M. von Bemmelen, *J. prakt. Chem.*, 1856, (1) 69, 84; *Jahresber.*, 1856, 603.

<sup>2</sup> See Chapter 4.

fore possible, leading to intermolecular esterification of the initial ester and forming finally immense resin molecules as an end-product.

The structure of phthalic glyceride is difficult to picture graphically on account of the complexity of glycerol itself. But if glycol, which is simpler than glycerol, is the reacting polyhydric alcohol, the reaction is probably as follows:

The initial ester may then combine intermolecularly to form a long chain-molecule:

If HO-X-OH is glycol (or another dihydric alcohol) and H-Y-H is phthalic acid (or any dibasic acid), the symbolic formula is:

The symbolic formula for phthalic glyceride differs from that of the glycol resin in having a branch-chain at each glycerol residue since there are three hydroxyl groups in glycerol to enter the reaction and only two in glycol.

**Classification of Alkyd Resins.** As might be anticipated the general properties of such resins vary according to the type of acid and alcohol employed.\* Kienle and Ferguson<sup>4</sup> distinguish three main classes: (a) Resins non-convertible by heat, namely, those formed from dihydric alcohols (glycol) and dibasic acids (phthalic anhydride), which do not gel on heating. (b) Heat-convertible resins, given by alcohols with not less than three hydroxyl groups (glycerol) and dibasic acids, or by dihydric alcohols and acids with not less than three carboxyl groups. These resins, as first produced by esterification, are converted by further heat treatment into infusible and insoluble products. (c) Element-convertible resins, those derived from unsaturated acids or alcohols, the properties of which are irreversibly altered by the oxidation of the unsaturated component.

One theory of resin formation was suggested by Kienle and Hovey<sup>5</sup> and further elucidated by Kienle.<sup>6</sup> Whenever the reactivity of an organic reaction is 2 to 2 (e.g., glycol and phthalic anhydride), where there are two functional groups, an amorphous or resinous substance results unless, as Carothers<sup>7</sup> has shown, the monomer can form a 5- or 6-membered ring. In these special cases cyclization would tend to take place and crystalline compounds would result. Thus with ethylene glycol and oxalic acid, a monomeric ester is formed. With glycerol and phthalic anhydride, the reactivity is 3 to 2, respectively, that is, there are three functional groups in glycerol but only two in phthalic anhydride. The tendency under these

\* These resins are often called "Glyptals," an incomplete anagram derived from the words gly(cerol) and p(h)yt(h)al(ic). This term has been adopted by the General Electric Co. for alkyd resins.

Hönel feels that the designation "glyptal" should be restricted to resins which on sufficiently prolonged condensation yield infusible and insoluble products. Such resins may have phthalic anhydride replaced by other polybasic acids, and within certain limits dihydric alcohols and monobasic acids may be substituted to confer modified properties. When such limits are exceeded, however, infusible limit products are not formed, and the term "glyptal" should then no longer be used. See H. Hönel, *Paint, Oil, Chem. Rev.*, 1931, 91 (22), 19; *Chem. Abs.*, 1931, 25, 3854.

The use of the name alkyd avoids the introduction of trade names.

<sup>4</sup> R. H. Kienle and C. S. Ferguson, *Chem. Met. Eng.*, 1932, 39, 599.

<sup>5</sup> R. H. Kienle and A. G. Hovey, *J.A.C.S.*, 1929, 51, 509.

<sup>7</sup> W. H. Carothers, *Chem. Rev.*, 1931, 8, 353.

conditions would likewise be to form chains but these chains could react with one another to form a highly complex, 3-dimensional pattern yielding on heating a large molecule which was both infusible and insoluble. (See Table 41.)

By the addition of monobasic acids to phthalic anhydride and glycerol, the course of the reaction is altered. The presence of the monobasic acid hinders the cross linkages of the chains. But with a highly unsaturated acid, cross linkages can occur through polymerization and oxidation of the side chains. This type of resin is known as the element- or oxygen-convertible type.\*

**Glycerol and Phthalic Anhydride.** The reaction between glycerol and phthalic anhydride since its discovery by Smith<sup>9</sup> in 1901 has been the subject of many investigations into the mechanism of resin formation. Kienle and Hovey,<sup>10</sup> in studying the rate of esterification of equivalent amounts of glycerol (2 mols) and phthalic anhydride (3 mols), found that reaction proceeded at first very rapidly, yielding within a minute, at the temperature investigated, a product corresponding to 50 per cent esterification, i.e., to a mixture of the monobasic mono-glyceride (I) and the dibasic diglyceride (II)

When esterification is about 60 to 70 per cent complete, the rate falls off, but proceeds more slowly up to and beyond the point at which gelation occurs. No aldehyde was detected in the reaction. This observation tends to invalidate the suggestion made by Barry, Drummond and Morrell,<sup>11</sup> that an intermediate aldehyde is the mechanism by which the alkyd resins are formed.

The preliminary formation of the monoesters was noted by Hönel,<sup>12</sup> who found that the continued heating of the infusible resin after gelation decreased its ability to swell with solvents, indicating the continuation of the process of esterification.

\* See Chapter 44.

<sup>9</sup> W. Smith, *J.S.C.I.*, 1901, 20, 1075.

<sup>10</sup> R. H. Kienle and A. G. Hovey, *J.A.C.S.*, 1929, 51, 509.

<sup>11</sup> T. H. Barry, A. A. Drummond and R. S. Morrell, "Natural and Synthetic Resins," D. Van Nostrand Co., New York, 1926. C. F. Peterson (British P. 250,949, 1926, to British Thomson-Houston Co., Ltd.; *Brit. Chem. Abs. B*, 1926, 988) found that the addition of small quantities of phenol-formaldehyde resin to the alkyd resin had a tendency to accelerate the polymerization of the latter. This observation tends to support the view that acrolein might be an intermediate form. The fact that the formation of the alkyd resin occurs more readily with polyglycerols than glycerol itself may indicate that the polymerization of the glycerol itself is involved in some manner. See T. H. Barry, *Ind. Chemist*, 1928, 4, 53; *Chem. Abs.*, 1928, 22, 2071.

<sup>12</sup> H. Hönel, *Kunststoffe*, 1931, 35, 76, 105, 123; *Chem. Abs.*, 1931, 25, 5047.

He therefore attributed resinification to the formation of compounds of high molecular weight solely by continued esterification of the acid esters first formed. Increase of the amount of glycerol causes the acid number of the mixture, immediately before it becomes infusible and insoluble, to decrease until finally the infusible state cannot be reached. When glycerol and phthalic anhydride are taken in such proportions as to form the mono- or the diester and heated, the reaction proceeds very slowly at 160°C. Above 230°C., the reaction is more rapid, but the tendency is to form hard resins. The greater the amount of phthalic anhydride, the greater is the tendency toward insolubility.<sup>13</sup>

Bozza,<sup>14</sup> on the other hand, regards the reaction as leading first to the esterification of the  $\alpha$ -hydroxyl groups of the glycerol, followed by a condensation process in which the molecular weight increases without increase in the degree of esterification, due to anhydride formation between the free acidic groups of adjacent molecules. Schlenker,<sup>15</sup> however, views the resins as long chains of glycerol molecules linked at the  $\alpha$ -positions through the carboxyl groups of alternating phthalic acid molecules, while the  $\beta$ -hydroxyl groups are esterified only in the later stages of the reaction.

Savard and Diner<sup>16</sup> made an extensive investigation of the kinetics of the esterification in question, and from the velocity constants of the process deduced that the initial step is the formation of the dibasic diglyceride already mentioned. This reacts with any excess of glycerol to form a neutral glyceride,

corresponding perhaps to conditions where an infusible resin cannot be formed. With excess of phthalic anhydride, the diglyceride reacts further at the  $\beta$ -hydroxyl group. In the absence of excess of either constituent, it is deduced that the diglyceride undergoes internal esterification. According to Hönel<sup>17</sup> it is this internal esterification that is responsible for the formation and the characteristic properties of the alkyd resins. He regards the first stage as giving rise (in equivalent mixtures) to a mixture of the mono- and diglycerides referred to above. With further heating, these react to give the condensation product as follows:

In the latter substance, two mols of glycerol are united to three mols of phthalic acid. The  $\beta$ -hydroxyl groups of the glycerol are still unesterified (corresponding

<sup>13</sup> S. Sugimoto, *Repts. Imp. Ind. Research Inst., Osaka, Japan*, 1932, 14 (13), 1; *Chem. Abs.*, 1934, 28, 4921.

<sup>17</sup> H. Hönel, *loc. cit.*, 19.

to the invariable rule that the  $\alpha$ -hydroxyl undergoes reactions first),<sup>12</sup> one-third of the acidity of the phthalic anhydride remaining unneutralized. This stage of the reaction corresponds to the absence of excess of either component, and to the experimentally found change in the rate of esterification when 33 1/3 per cent free acid remains. The theoretical relationship between molecular weight and acid number,<sup>13</sup> representing various stages in the esterification of phthalic anhydride and glycerol, is shown below, where P represents phthalic acid and G, glycerol. A terminal P implies the presence of a carboxyl group and a terminal G, a dihydroxy group.

Table 41a.—*Theoretical Relationship between Molecular Weight and Acid Number in Glycerol-Phthalic Anhydride Esters.*

Name	Type Formula	Molecular Weight	Acid Number
Monoglycerol monophthalate	G—P	240	233
Diglycerol diphthalate	G—P—G—P	462	121
Triglycerol triphthalate	G—P—G—P—G—P	684	82
Tetraglycerol tetraphthalate	G—P—G—P—G—P—G—P	906	62
Monoglycerol diphthalate	P—G—P	388	280
Diglycerol triphthalate	P—G—P—G—P	610	184
Triglycerol tetraphthalate	P—G—P—G—P—G—P	832	135
Tetraglycerol pentaphthalate	P—G—P—G—P—G—P—G—P	1054	106

Further esterification, now involving the  $\beta$ -hydroxyl groups, might conceivably proceed internally, forming such a glyceride<sup>14a</sup> as

This is, however, unlikely, as the limit product is almost completely soluble in very dilute potassium hydroxide, requiring in fact, only as much alkali as is required to neutralize the free acid. The progressive decrease in acidity and corresponding increase in resin-like properties can, however, be far more readily explained by the esterification of a hydroxyl group by the acid of another molecule thus:

<sup>12</sup> Cf. A. Fairbourne and G. W. Cowdrey, *J.C.S.*, 1929, 139.

<sup>14a</sup> This is a hypothetical formula. According to E. W. Spanagel and W. H. Carothers (*J.A.C.S.*, 1936, 57, 299), cyclic esters involving 8-membered rings have never been prepared. Although it is a relatively simple matter to obtain cyclic polybasic acid-polyhydric alcohol esters in a monomeric form when the ring consists of 6 atoms (e.g., glycol oxalate) and also when the ring consists of a large number of atoms, the monomers corresponding to rings of 7 or 8 atoms are practically impossible to form.

By the continuation of the above process, formation of giant molecules may be visualized, consisting of long-branched chains of the type shown, which may perhaps further condense to ring structures of a high order. The length of such chains, and the corresponding colloidal properties of the resin, thus depend primarily on the length to which the heat treatment is carried beyond the point at which internal esterification commences.

Kienle and Race<sup>20</sup> studied the change in the electrical, chemical and physical properties of the modified and unmodified alkyd resins by measuring the changes in the D.C. resistance of the melts held at 190-195°C. During the formation of the unmodified alkyds there is a progressive increase in the electrical resistance with time (see Fig. 124). It may be seen that the further away the resin is from

<sup>20</sup> R. H. Kienle and H. H. Race, *Trans. Electrochem. Soc.*, 1934, 65, 231; *Brit. Chem. Abs. B*, 1934, 811.

the heat-convertible, the more the curve shifts to the right indicating higher resistance values for the same percentage of esterification. Inasmuch as the per cent esterification gives the number of carboxyl and hydroxyl groups, the higher resistance must be due to a factor other than ionization. Kienle and Race ascribe this to fluidity or mobility. For a given per cent esterification the shift from the heat-non-convertible (mobile) to the heat-convertible (less mobile) is accompanied by an increase in resistance. On this basis glycol phthalate gives a lower resistance than glycerol phthalate. Glycol phthalate, which produces a chain molecule rather than a criss-cross, three-dimensional molecule, readily approaches complete esterification without gelation and with a very high value for the resistance.

No simple or adequate explanation may be advanced to correlate the electrical characteristics. Debye's<sup>20</sup> theory of polar orientation, although mathematically

FIG. 124.—Comparison Between Per Cent Esterification and Electrical Resistance of Typical Alkyd Resins During Formation. (R. H. Kienle and H. H. Race.)

rigid only for dilute solutions, may be a contributing factor in both the heat-non-convertible resins and in the heat-convertible types at high temperatures. For the latter, however, it seems more probable that during gelation a cellular structure is formed of good insulating properties containing pockets of liquid or plastic semi-conductors.

A similar conclusion has been reached by Winning and Williams<sup>21</sup> from a study of the adsorptive properties of alkyd resins and the effect of curing. Their results agree with the assumption of giant molecules as the fundamental structural units, which increase in size and compactness, the chains lengthening and ramifying during the curing process, thereby decreasing the pore space and the adsorptive power. Corresponding to the decrease in adsorptive properties is a decrease in the tendency to disperse in a solvent, although as the pores take up solvent the resin swells, and can retain much solvent or vapor. The formation of ramified irregular chains is probably a characteristic property of the heat-convertible alkyd resins.

<sup>20</sup> P. Debye, "Polar Molecules," Chem. Catalog Co., New York, 1929.

<sup>21</sup> C. H. Winning and J. W. Williams, *J. Phys. Chem.*, 1932, 36, 3915; *Chem. Abs.*, 1932, 27, 651; *J.A.C.S.*, 1932, 55, 2560.

Wornum,<sup>22</sup> on the other hand, emphasizes the physical features. Two separate aspects must be considered in the colloidal behavior of ethylene glycol- and glycerol-phthalic anhydride: first, in the building up of the micelles and also the larger or secondary flocculates and, second, in the spatial distribution of the units throughout the system. The latter bears a distinct relation to phase stability which determines, among other things, the sol-gel transformation.

In a system such as ethylene glycol-phthalic anhydride, Wornum believes that the formation of larger units of the dispersed phase can only be accomplished through the operation of secondary valence forces. At high temperatures and in the absence of these valence forces, any aggregate must of necessity be of an evanescent character and, therefore, no gelation occurs. At lower temperatures these valence forces would become active, the micelles and secondary flocculates would then assume a more stable form resulting in a state of reversible gelation.

In the case of phthalic anhydride and glycerol, the conditions are less simple. The secondary valence forces act both at high and at low temperatures but, in addition, at higher temperatures it is necessary to consider the primary valence forces. Under these conditions larger units would easily be built up and the formation of irreversible micelles and irreversible flocculates would lead to irreversible gelation.

By means of specific-viscosity determinations<sup>23</sup> Houwink and Klaasens<sup>24</sup> have tested the concept that at temperatures below 180°C. only the  $\alpha$ -hydroxyl groups of the glycerol are active. At higher temperatures, the  $\beta$ -hydroxyl group enters into the reaction with the formation of a 3-dimensional polymer.

**Glycol Resins.** The esterification of glycol and other dihydric alcohols by dibasic acids, like the esterification of glycerol, leads to the formation of highly polymerized resinous products. The glycol resins differ however from the glycerol resins in that, even when esterification is carried to the limit, an infusible product is not formed. The glycol resins represent, then, the heat-non-convertible resins of Kienle and Ferguson.<sup>25</sup>

Taking the case of ethylene glycol and succinic acid as an example the first product of esterification will be the monoester.

This might, according to circumstances, either undergo internal esterification, giving the neutral, monomeric ester

or else the free acid groups may esterify the free hydroxyl of another molecule, resulting in an acidic dimeric ester.

The first reaction leading to cyclization is excluded on the basis of the rule of Carothers;<sup>26</sup> consequently the intermolecular reaction would be expected. The process may thus be considered to proceed almost indefinitely, with the formation of linear polyesters of the general type:

in which the long chain-like molecule may be built out of many units. As may be

<sup>22</sup> W. E. Wornum, *Chem. Age (London)*, 1934, 30, 245. See Chapters 3 and 4.

<sup>23</sup> See Chapter 4.

<sup>24</sup> R. Houwink and K. H. Klaasens, *Kolloid.-Z.*, 1935, 70, 329.

<sup>25</sup> R. H. Kienle and C. S. Ferguson, *loc. cit.*

<sup>26</sup> W. H. Carothers, *loc. cit.*

seen, the linear polymer differs distinctively from the extensively branched chains of the glycerol phthalate type. To this difference in structure of the final resin may be attributed variations in physical properties such as the gelation of the glycerol resins to an infusible product and the usual absence of such a property on the part of the glycol resins.

**Glycol and Carbonic Acid.** The neutral ester of glycol with carbonic acid, ethylene carbonate, is the 5-membered cyclic compound

As might be anticipated from the stereochemistry of 5-membered rings, the tendency is, therefore, toward cyclization to the simple ester rather than toward polymerization to resins. This is, in fact, the case;<sup>27</sup> ethylene carbonate is formed in good yield either by the action of carbonyl chloride (COCl<sub>2</sub>) or of 1 mol of chloroformic ester on ethylene glycol. In the latter case, the carbethoxy-glycol first formed eliminates alcohol intramolecularly, rather than intermolecularly, which would lead to polymerization.

The carbonates of the glycol monoethers, and especially of diethylene glycol ether,

are high-boiling liquids which have been suggested as possible lacquer plasticizers.<sup>28</sup>

While ethylene glycol yields with carbonic acid only the monoester, polyesters may be obtained from other dihydric alcohols, all corresponding in composition to chains made up of the unit  $-\text{O}-(\text{CH}_2)_x-\text{O}-\text{CO}-$  which may recur 8 to 22 times.

Trimethylene carbonate exists both as the monomeric ester (m.p. 48°C.),

and as a glass of 38 to 45 structural units. Polymerization takes place on heating and is catalyzed by a trace of potassium carbonate. The glassy polymer is found by x-ray examination to be crystalline.<sup>29</sup>

By heating the linear polyesters with catalysts<sup>30</sup> it is possible in certain cases to bring about a smooth depolymerization to the monomeric or dimeric esters. The ratio of the monomer to the dimer is determined first on the nature of the ester, that is, its unit length and secondly on the experimental conditions.

Tetramethylene carbonate gives rise to a considerable amount of tetrahydrofuran, arising undoubtedly by the loss of carbon dioxide from the structural unit. The chief product was a 14-membered ring, a dimer which has been prepared by Ruzicka.<sup>31</sup> Carbonates of penta-, hexa-, hepta-, octa- and nonamethylene were chiefly dimeric. Decamethylene carbonate, however, yielded a considerable amount of monomer, the same being true of undecamethylene carbonate.<sup>32</sup>

<sup>31</sup> L. Ruzicka and M. Stoll, *Helv. Chim. Acta*, 1923, 11, 1159; *Chem. Abs.*, 1929, 23, 1110.

<sup>32</sup> J. W. Hill and W. H. Carothers, *J.A.C.S.*, 1933, 55, 5031.

**Glycol and Oxalic Acid.** The six-membered cyclic ethylene oxalate forms an intermediate stage between simple and polyesters. By the action of ethylene glycol on ethyl oxalate,<sup>33</sup> there is obtained a white powdery polymeric product, which from analyses and molecular weight determinations appears to be approximately of the composition

On heating the polymer in a vacuum, the monomeric ethylene oxalate, (m.p. 143°C.)

is formed in 50 per cent yield, but the solid substance undergoes polymerization in the course of a few days, being finally transformed into an insoluble form (m.p. 170-173°C.), in which it is possible to distinguish two polymers: one of m.p. 159°C. representing about 20-fold polymerization, the other probably higher.

Propylene glycol forms with ethyl oxalate a colored viscous resin from which, on heating in vacuum, monomeric propylene oxalate

was obtained. This did not polymerize at the ordinary temperature, but could be converted at 140°C. to a completely insoluble polymer melting at 176-178°C.

Cyclization would not be anticipated in the reaction between trimethylene glycol ( $\text{HO—CH}_2\text{—CH}_2\text{—CH}_2\text{OH}$ ) and ethyl oxalate inasmuch as this would necessitate the formation of a seven-membered ring. The reaction takes place intermolecularly yielding a product of molecular weight of about 2000, i.e., a 15-20 structural-unit polymer. On distillation a small amount of dimer,

is formed.<sup>34</sup> Hexamethylene glycol and decamethylene glycol also give rise to linear polymers of the same type.

**Glycol and Succinic Acid.** By the action of succinic acid on excess glycol at 180°C., and subsequent removal of the excess glycol, a polymeric crystalline neutral glycol succinate is formed,<sup>35</sup> (m.p. 102°C.), which may be taken as typical of the glycol esters of dibasic acids. This substance may be represented by the formula,

consisting of 23 of the simple structural units,

linked together.<sup>36</sup> In the presence of excess of succinic acid, and with shorter times of heating there is a tendency to the formation of less-highly condensed, lower-melting products. Substances containing 6, 9, and 12 of the basic structural units in the molecule were thus obtained. In all cases, even with 2 mols of succinic acid per mol of glycol, high-molecular products were formed, and not the diacid ester,

<sup>33</sup> W. H. Carothers, J. A. Arvin and G. L. Dorough, *J.A.C.S.*, 1930, 52, 3393.

<sup>34</sup> W. H. Carothers, J. A. Arvin and G. L. Dorough, *loc. cit.*

<sup>35</sup> W. H. Carothers and G. L. Dorough, *J.A.C.S.*, 1930, 52, 711.

<sup>36</sup> The preparation of glycol esters of dibasic acids is also described by F. B. Sherland, *J.A.C.S.*, 1935, 57, 115.

The compound,  $\text{HO}-(\text{CH}_2)_2\text{O}-\text{CO}-(\text{CH}_2)_4-\text{CO}-\text{O}(\text{CH}_2)_2\text{OH}$ , formed as a viscous, non-volatile liquid by heating neutral ethylene succinate with glycol, is reconverted into the neutral ester and glycol on slow heating in vacuum.

These neutral ethylene succinates when dissolved in chloroform and spread on 0.01 *N* hydrochloric acid form stable unimolecular films. The molecular chains, so formed, are flexible and may be packed closely before disruption by compression.<sup>37</sup>

That esterification continues progressively, with the formation of longer, more-highly polymerized molecules, on continued heating, is indicated by Kienle and Hovey's<sup>38</sup> study of the rate of esterification of glycol with phthalic anhydride. As in the case of glycerol, rapid initial esterification was followed by a slower steady decrease in the free acidity, but no irreversible gelation occurred, the flow point and viscosity rising with time to final steady values indicating completion. Hönel<sup>39</sup> states that the monoester,  $\text{HO}-\text{CH}_2-\text{CH}_2-\text{O}-\text{CO}-\text{C}_6\text{H}_4-\text{COOH}$ , corresponding to the initial rapid esterification, can be isolated.

**Properties of the Polymethylene Polyesters.** The esters of dibasic acids with dihydric alcohols are thus regarded in every instance as linear polymers. Carothers and Dorough<sup>40</sup> found that in all cases the limiting length of chain, under ordinary conditions, was about 200 atoms. Although diethylene glycol carbonate,

$\text{O}(\text{CH}_2)_2-\text{O}-(\text{CH}_2)_2-\text{O}-\text{C}=\text{O}$ , ethylene malonate and decamethylene phthalate are liquids, most of the esters are found by x-ray methods to be microcrystalline solids.

The physical properties of the substances depend largely on the nature of the structural units of which they are composed. Increase in the length of the polymethylene chains,  $-(\text{CH}_2)_n-$ , increases the solubility in organic solvents and diminishes the viscosity of the molten ester although this is always relatively high.<sup>41</sup> Where the ester groups are separated by polymethylene chains the substances may be crystalline. Less symmetrical polyesters, such as glycol phthalate, are resins (either transparent glasses or balsams). The crystalline esters also, when melted and cooled, yield opaque masses, which may be brittle and porcelain-like or soft and waxy. The waxy quality increases with the length of the polymethylene chains.

A special polyester found by Carothers and Van Natta<sup>42</sup> to possess toughness and elasticity was hexamethylene carbonate, which, though crystalline, separates from solution as opaque horny flakes. The reason for this property in hexamethylene carbonate alone is obscure.

As stated above, under normal working conditions the limit of condensation is a resin with a molecular weight of about 3000. Carothers and Hill<sup>43</sup> noted that by continuing the heat treatment in high vacuum, the so-called molecular still, the process could be carried further, yielding "super-polyesters" of modified properties. The properties of the products thus obtained may be exemplified by the polyethylene succinate so formed, which forms a tough, slightly elastic, horny mass at 97°, but flows only at a higher temperature. The melt may be drawn out into strong, pliable fibers; several of the esters, indeed, notably ethylene sebacate and the ester produced by auto-condensation of  $\omega$ -hydroxypentadecanoic acid, can be cold-drawn. It is not possible to spin filaments from the polyester of hydroxy-decanoic acid unless the molecular weight reaches about 7000. Cold drawing does not appear until the molecular weight approaches 9000. This relation between

<sup>37</sup> S. A. Moss, *J.A.C.S.*, 1934, 56, 41.

<sup>43</sup> W. H. Carothers and J. W. Hill, *ibid.*, 1932, 54, 1559.

the fiber and molecular length is important when it is seen that a fiber appears to require a molecule whose weight is at least 12,000 and whose length is not less than 1000 Å.

The glycol-phthalate resins also belong to this class of derivatives and have been proposed<sup>44</sup> in the production of artificial silk but, though lustrous threads may be obtained, they are exceedingly fragile according to Carothers and Hill.<sup>45</sup>

**Resins of Mixed Type.** Resins of the ethylene succinate type have been seen to possess the long-chain molecular structure favorable to the formation of flexible fibers; but to be non-heat-convertible. Kienle and Schlingman<sup>46</sup> have described heat-convertible flexible resins formed by introducing a proportion of the rigid, heat-convertible glycerol-phthalate into ethylene succinate. The resulting resins therefore comprise flexible, two-dimensional chains of the ethylene succinate type, which may be pictured as follows:

The resins are convertible by heat owing to cross-tying occurring between the glycerol phthalate units. The flexibility and hardness of the resins formed depend on the proportion of the two types present, increase in either the proportion or the chain length of the dihydric alcohol-dibasic acid component increasing the flexibility.

in a transparent state and offer a non-inflammable substitute for celluloid. The very flexible resins display a remarkable sound-absorbency and facility for dampening vibrations. Such resins have found application further as lacquer plasticizers, as a base for heat- and oil-resistant varnish cloths and as gaskets.

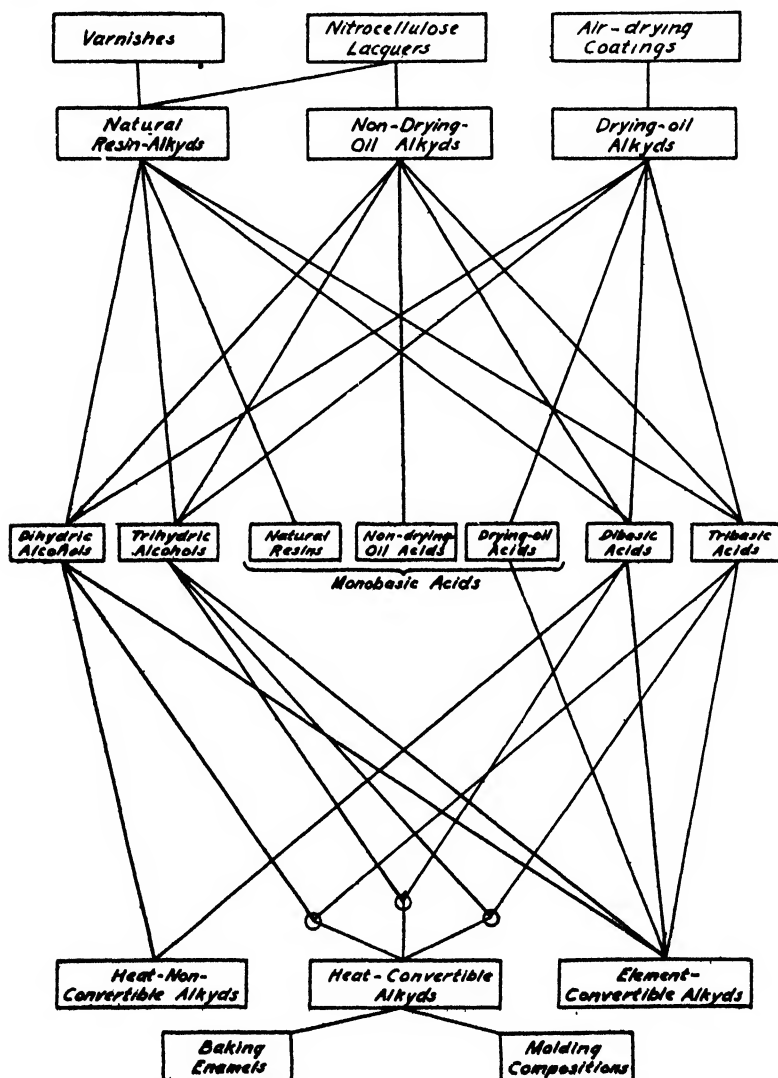

FIG. 125.—Relationships Among Alkyd Resins.

**Monobasic Acid-Modified Resins.** Addition of monobasic acids to the alkyd type of resin modifies the properties considerably. The alkyd resins, according to the type of monobasic acid may be non-drying, semi-drying or drying. The non-drying type of alkyd resin is used mostly in nitrocellulose lacquers as a resin or plasticizer or both. Castor oil also finds use in these nitrocellulose lacquer

alkyds. The semi-drying-oil alkyds can be baked at high temperatures and show no tendency to wrinkle under this treatment. The short-drying alkyds may be baked rapidly and exhibit unusual hardness and good adhesion.<sup>47</sup> They can also be air-dried.

By the interaction of linseed oil fatty acids (1 equivalent) and phthalic anhydride (2 equivalents) on glycerol (3 equivalents), a product is obtained simulating bodied linseed oil. It displays on heating both the element-convertibility of the drying oils and the heat-convertibility of the alkyd resins, according to Hönel.<sup>48</sup>

**Alkyd Resin Modifications.** Due to various modifications, alkyd resins have been classified in several ways. Krumbhaar<sup>49</sup> suggests the following groups: (1) Straight alkyds, (2) phenol-modified alkyds, (3) phenol-modified and oil-extended and (4) non-phenolic, modified by natural resin acids. Malowan<sup>50</sup> uses the classification: (1) Unsaturated modifications containing fatty acid residues and compatible with nitrocellulose lacquers, (2) modified with natural resin acids, (3) unsaturated containing drying oils and (4) mixed types from natural and synthetic resins.

The divisions which will be adopted in this instance depend upon the use of: (1) non-drying oils and acids, (2) natural resins, (3) various drying oils and acids and (4) other synthetic resins. In Figure 125 are shown the inter-relationships and ramifications of the alkyd resins. The very center of the diagram reveals the various ingredients used in making up the resins. From the ingredients it is possible to trace the various types which may be synthesized. Thus the heat-non-convertible resins are prepared from dihydric alcohols and dibasic acids. Heat-convertible alkyds may be made from dihydric alcohols and tribasic acids, from dihydric alcohols and tribasic acids or from tribasic acids and trihydric alcohols. It will be noted that the element-convertible alkyds correspond to the drying-oil alkyds. Use of such acids as non-drying or natural resin acids yields other derivatives which do not correspond to the convertible and non-convertible types.

## Chapter 42

### Alkyd Resins. Production

The reaction products of polyhydric alcohols and polybasic acids form a very important group of resinous substances. Glycol, glycerol and their homologues are typical polyhydric alcohols. The more common polybasic acids include phthalic, tartaric, citric, succinic, maleic and malic, and in addition there are many other acids of this type which are less easily available.

Phthalic glyceride, the reaction product of glycerol and phthalic anhydride, serves as a basis of comparison for the resins of this group. This chapter includes the investigations relating to this resin and others which may be formed from polybasic acids and polyhydric alcohols, that is, two-component resins. When part of the polybasic acid or polyhydric alcohol is replaced by other types of acid or alcohol, or when any other ingredient enters into the composition, more complex resins having different properties are obtained.

In 1901, in an attempt to make a phthalein dye, Watson Smith<sup>1</sup> heated for a long time nearly to boiling a mixture of 2 mols glycerol and 3 mols phthalic anhydride (the proportions corresponding to diglyceryl triphthalate) and on cooling, a solid resin-like, perfectly transparent and strongly refractive substance was obtained. This substance was insoluble in water, but soluble in an excess of glycerol on heating. From the solution in glycerol the addition of water caused the separation of white oily drops soluble in alcohol and ether. Similar resin-like masses were made using zinc chloride; these deliquesced and became sticky on exposure to air. Upon distilling *in vacuo* to remove the excess of glycerol a mass resembling glass slag was obtained; the end point of the distillation was noted when frothing set in. The same compound was obtained regardless of whether an excess of either phthalic anhydride or of glycerol was used. The resin was easily saponified by alkali hydrates. Smith varied the fusibility of the resin by stopping the vacuum distillation of the glycerol at some intermediate point. The initial melting point (190°C.) and the decomposition point (220°C.) were not far apart. At the latter temperature the resin did not completely melt and crystals of phthalic anhydride distilled off which were deposited on the sides of the tube. The resin ignited readily and burned with a bright flame but softened without melting. Smith recommended it as a cement for glass and earthenware.

The next investigator of phthalic glyceride was Callahan.<sup>2</sup> He gave certain details of operation as follows: One part by weight of glycerol and 2 parts of phthalic anhydride are heated slowly. At 100°C. the mixture forms a clear liquid and as the heating continues, distillation occurs to a slight extent. At 185°C. the temperature rise should be checked until distillation ceases. Then the heating is continued at a higher temperature, about 210°C., until the first stage of the reaction is completed. This point is ascertained by withdrawing small samples, cooling and observing if these are hard and brittle without stickiness. The resin is yellowish and transparent. If the heating is continued at 210°C., further change

<sup>1</sup> W. Smith, *J.S.C.I.*, 1901, 20, 1075.

<sup>2</sup> M. J. Callahan, *U. S. P.* 1,108,329, Aug. 25, 1914; *Chem. Abs.*, 1914, 8, 3506.

takes place with the evolution of heat. At 275°C. a violent ebullition sets in and there results a brittle infusible mass filled with cavities. Even at 210°C. some vesiculation occurs.

Callahan<sup>a</sup> prevented vesiculation when carrying out the transformation or polymerization to an insoluble product by heating at 85-100°C. (or even 135°C.) for a considerable period, say 15 to 20 hours. The product is a homogeneous dense resin which softens at temperatures above 40°C. but never actually melts without decomposition. It may be molded with a filler in various ways. The insoluble product possesses high dielectric strength and good insulating properties. Alkali saponifies the resin to regenerate glycerol and the corresponding phthalate. Callahan also proposed to employ glycol and carbohydrates (glucose, sucrose, starch, and cellulose) instead of glycerol.

The resin described above does not represent the final product. Callahan found this resin to be affected by water. On standing for several weeks in contact with water the surface of the insoluble resin became white and cheesy. Long exposure to the weather caused it to become white and crumbly. Callahan termed this product an intermediate resin and made further experiments on the effect of heat treatment leading to a final form having notable resistance to water. The procedure he recommended is to heat the intermediate product for 5-10 hours at 180-250°C. At this temperature condensation is completed and any traces of free glycerol are eliminated. The resin is insoluble in all the usual solvents but like the intermediate product is soluble in glycerol. The final product is not attacked in the cold by alkaline solutions. At 140°C. the resin becomes leathery and may be bent or molded.

The water formed during esterification distills off as fast as it is formed, especially if the heating is carried out in an open vessel, or (as is usually the case) under a short air-condenser. It may also be eliminated by the addition of an inert, water-insoluble organic liquid capable of forming a pseudo-azeotropic mixture with water. Xylene, cyclohexane or acetylene tetrachloride may be used.<sup>4</sup> The reaction can also be carried out in the presence of high-boiling inert liquids like tetralin or dekalin which are later distilled off along with the water of reaction.<sup>5</sup>

The resin produced from glycerol and phthalic anhydride is practically colorless when the condensation is carried out in an atmosphere of carbon dioxide or of hydrogen, or in a vacuum.<sup>6</sup> Another method of treating the resin is to spray the aqueous mixture into an inert atmosphere.<sup>7</sup>

#### STAGES OF RESINIFICATION

According to Weisberg<sup>a</sup> the condensation of glycerol with polybasic acids takes place in three stages.

A. The initial condensation product is soluble in acetone and is fusible. Its melting point seldom exceeds 120°C. This resin is not resistant to cold water but on further heating passes over into a resin of class B.

B. This resin is an intermediate condensation product, practically insoluble in acetone and difficultly fusible, although it can be molded under heat and pressure. Like the resins of class A it is not resistant to cold water. On heat treatment it is converted into a resin of class C.

<sup>a</sup> L. Weisberg, U. S. P. 1,413,144 and 1,413,145, Apr. 18, 1922, to Barrett Co.; *J.S.C.I.*, 1922, 42, 667A. British P. 173, 225, 1921; *J.S.C.I.*, 1923, 42, 667A.

C. This resin represents the final condensation product. It is insoluble in acetone and infusible, but it can be molded under heat and pressure. It is resistant, moreover, to both cold and boiling water. The resin produced from glycerol and phthalic acid is very brittle and the addition of an aliphatic acid tends to reduce brittleness, although probably diminishing resistance to water. In fact, a tougher and more elastic product is obtained when a substantial proportion of a dibasic aliphatic acid (succinic, malic, tartaric, maleic or fumaric acid) is present.

The C-stage products are superior to B-stage resins in hardness and resistance to water and solvents. They are intractable substances, however, and require drastic treatment to make them useful unless they are formed under such conditions that they can be used directly as produced, as for example, in molded articles or baked coatings.

The B-stage resins swell rather rapidly and become gelatinous in hot acetone. Weisberg<sup>22</sup> used glycerol phthalate in the B-stage. The resin is treated with hot acetone and mixed with fillers. The acetone is then distilled off and the product molded. Curing time is shorter than that of a molding composition made from resin in the A-stage. Wright<sup>9</sup> also used the B-stage with swelling agents along with a plasticizer. This plasticizer may be added directly or the resin may have its own plasticizer in the form of an ester from the ingredients used. One may also dissolve the A-resin in a B-resin solvent (e.g., cyclohexanol) and heat the solution to convert the resin into the B-state; the filler being introduced at any convenient stage before pressing.<sup>10</sup>

It is possible to prepare colorless resinous bodies, which are hard, tough and infusible, from the initial reaction products of phthalic anhydride and glycerol by sufficiently prolonged baking of the resin at a moderate temperature. The time necessary to achieve this result is, as compared with most chemical reactions, very long, but varies with the size of the piece or block, with the temperature and with the degree of hardness desired. For molded blocks or slabs of moderate size a heat-treatment of several weeks or even months may be necessary. For example, blocks approximately  $4 \times 4 \times \frac{1}{4}$  inches require heating at about 125°C. for a period of 12 weeks.

Schmidt<sup>11</sup> heated a mixture of one part by weight of glycerol with 2 parts of phthalic anhydride to about 150° to 175°C. until the first condensation was complete. The resulting condensation product was poured into molds, and maintained at about 90°C. until it assumed a firm, rubbery consistence. The temperature was then gradually increased to about 125°C. and maintained until the resin became infusible. The product is transparent, free from bubbles or flaws, practically colorless, tough, infusible, and sufficiently thermoplastic to allow it to be molded under heat and pressure. The final hardening may also be carried out in a mold under pressure at a temperature of about 170°C. It is advisable to use molds made of aluminum or stainless steel or to line the molds with aluminum or vitreous enamel.<sup>12</sup> Another resin of the glycerol phthalate type which is insoluble in water, neutral and soluble in organic solvents is obtained by carrying out the reaction at a low temperature and by separating the neutral glycerol phthalate formed during the reaction. The reaction mass is taken up in an organic solvent

(acetone or alcohol) which dissolves the neutral phthalates; addition of alkali precipitates the resin.<sup>13</sup>

#### ACCELERATION OF CONVERSION

Resins may be converted to the infusible-insoluble, or C-stage, without the formation of a frothy mass if the intermediate form is heated under pressure, or at a moderate temperature without pressure, but these operations are usually unsatisfactory on account of the length of time required. It is important commercially to shorten the curing time as much as possible.

If the initial resin is heated at 205°C. to a stage just short of its conversion to the insoluble C-stage, the period of baking is reduced. As soon as a sample of resin, cooled to about 180°C. shows signs of stringing, the entire mass is poured out into shallow pans to cool it rapidly, and the resin is afterward baked at a moderate temperature until it becomes infusible.<sup>14</sup>

Another way of controlling the conversion to the infusible stage is to heat the initial resin until a sample is hard and brittle when cold. The entire mass is then allowed to cool and is pulverized. This finely divided resin is heated in a rotating oven at 100°C., the temperature is gradually increased as the resin gets harder, and finally it is heated for about 4 hours at 225°C., the treatment being stopped before the particles reach the stage of complete infusibility. The powder thus obtained may be used directly for molding.<sup>15</sup>

Wright and Bartlett<sup>16</sup> dissolved the initial resin in an inert, high-boiling solvent (diethyl phthalate or benzyl benzoate) and heated the solution until the resin was almost converted to the insoluble stage. A solution of the resin in diethyl phthalate (b.p. 295°C.) is heated to between 210-290°C. without a reflux condenser (to eliminate volatile materials) until the resin is just short of the insoluble stage. After heating, the solution is poured into benzene which precipitates the resin as a white curd, which is dried and ground to a powder. The product is slowly soluble in acetone and unlike ordinary glycerol phthalate is non-corrosive to metals. It is converted to the final hard form in a shorter time than a resin which has not been treated in this way.

A similar procedure was used by Schmidt.<sup>17</sup> In this instance the phthalic anhydride and glycerol were dissolved in diethyl oxalate or glycol diacetate and the solution was heated to the stage of incipient gelatinization of the resin. A medium-boiling solvent is then added to form a solution of highly polymerized resin.

Adams<sup>18</sup> allowed the resin to reach the infusible vesiculated condition by heating it to about 300°C. and ground the mass after cooling. Although the resin in this condition is insoluble in all organic solvents in the cold, it may be dissolved by protracted heating at a high temperature under pressure in a large number of organic liquids which are solvents for both glycerol and phthalic anhydride, among which may be mentioned glycol diacetate, diethyl phthalate, acetone, acetone oils, benzyl

benzoate, benzyl acetate, toluidine, benzyl alcohol, cresol, tricresyl phosphate, triacetin, anisol, o-cresyl benzoate, ethyl lactate, indene and indene polymer. Heating in a closed container for about 36 hours at 170°C. is necessary for solution.

The temperature of hardening soluble resins made from polyhydric alcohols and polybasic acids is reduced by treatment with an acid (sulphurous, hydrochloric, hydrofluoric, formic or acetic acids) of stronger acidity than the acid component of the resins.<sup>19</sup>

*Courtesy Modern Plastics*

FIG. 126.—Buttons Before and After Tumbling Operation.

The time required to convert the resin to the intusible state may also be reduced by treating the initial resin with an acid anhydride or an acid chloride. The excess is removed by heating the resin at ordinary or reduced pressure. For example, 100 parts by weight of fusible glycerol-phthalate resin are treated with 10 parts of acetic anhydride at 120°-130°C. for about an hour. Heating the resulting product at 125°-130°C. in a vacuum removes the excess reagent and yields a resin which cures more rapidly than an untreated one.<sup>20</sup>

Arsem<sup>21</sup> found that sulphonic acids have an accelerating effect both in the

formation of the initial resin and in the conversion of this product to the infusible state. When 1 to 5 per cent of such acids as benzene sulphonic, 1-naphthylamine-4-sulphonic or 4-aminotoluene-2-sulphonic acids is used, the time required to form the initial resin from phthalic anhydride and glycerol may be reduced to only one-sixth of the period necessary and the initial resin hardens in a relatively short time. Neutral phenyl benzenesulphonate and other sulphonic acid esters have been used by Carswell.<sup>22</sup>

The addition of zinc oxide or calcium oxide lowers the solidification temperature.<sup>23</sup> Wright<sup>24</sup> recommended heating the resins with dehydration catalysts (calcium oxide, magnesium oxide, zinc oxide or finely divided iron or zinc) to convert them to the insoluble form. Metallic soaps, incorporated with the resin during its formation, yield a tougher and more shock-resistant product which sets more quickly under heat treatment. Adams<sup>25</sup> heated a mixture containing 68.8 parts of phthalic anhydride, 28.3 parts of glycerol and 2.9 parts of cobalt linoleate to form a similar resin. Lead oleate, aluminum stearate and metallic linoleates are other soaps and salts which act in the same way.

Rosenstein and Hund<sup>26</sup> used silica gel<sup>27</sup> as an esterification catalyst in the reaction between glycerol and phthalic anhydride; Ushakov<sup>28</sup> employed mineral salts, metallic oxides or metals, with or without pressure.

Blumer<sup>29</sup> reduced the acidity of the resin and removed uncombined initial materials both in one step by treating the resin in an intermediate stage of condensation through use of ethyl, methyl, butyl or propyl alcohols. For example, the condensation product derived from glycerol, phthalic acid and citric acid is dissolved in a small amount of alcohol or in alcoholic benzene; the solution is separated into two layers by the addition of ethyl alcohol. The residual resin has a much improved heat-hardening rate.

#### RETARDATION OF CONVERSION

If fillers are to be impregnated with the molten resin a difficulty arises, in that hardening takes place rendering impregnation difficult. Callahan<sup>30</sup> avoided the hardening by adding naphthalene (preferably 13-18 per cent) to the resin. Monochloro- and tetrachloronaphthalene or anthracene can also be used. These substances allow the resin to liquefy at a lower temperature than that necessary for the straight resins, and consequently gelation occurs less quickly. The addition of from 1-10 per cent of boric acid is said to retard the formation of insoluble masses.<sup>31</sup> Urea or thiourea added to the polyhydric alcohol and polybasic acid resin causes the resin to gel or polymerize more slowly.<sup>32</sup>

## IMPROVING FLEXIBILITY

Various plasticizers (soft resins or liquids) may be mixed with phthalic glyceride to improve its flexibility. Callahan<sup>33</sup> and Arsem<sup>34</sup> used succinic glyceride which was formed *in situ*. Dawson<sup>35</sup> found m-dinitrobenzene, acetanilide and ethyl benzoate to be useful with citric glyceride.

The disadvantage of using the glycerides of aliphatic dibasic acids (succinic) to increase the flexibility of phthalic glyceride is that the effect is not permanent. When heated for a long time or when aged the mixed resin becomes brittle and tends to have a high acid number. Glycols give highly esterified bodies which remain soft for an indefinite period but they retain solubility at all times and do not cure. Kienle and Rohlf<sup>36</sup> have suggested the incorporation of glycol succinate with phthalic glyceride in such amounts that the composition cures when heated at a high temperature. About one mol of each resin may be used. The resins may be prepared separately and then mixed, or all ingredients may be heated together at 180-200°C. Curing is carried out at 150°C. and a soft, flexible product is obtained.

High-boiling solvents were used to increase flexibility by Conover,<sup>37</sup> who mixed 15 parts of diethyl phthalate with 85 parts of freshly prepared phthalic glyceride and heated the solution to 150°C. A soft, light-colored resin was obtained which could be converted into a flexible, infusible form by heating to a high temperature. Kienle<sup>38</sup> added dibutyl phthalate, triphenyl phosphate, triacetin or aniline to overcome the brittleness of phthalic glyceride.<sup>39</sup> The addition of furfural increases flexibility but also has a tendency to darken the color. Conover<sup>37</sup> heated a mixture containing 92 parts of glycerol and 148 parts of phthalic anhydride at 210°C. for an hour, allowed the temperature to fall to 140°C. and added 48 parts of furfural, producing a soft, dark-colored mass. This product is converted to the infusible form when heated, the conversion being about 10 times as rapid as that of the resin in the absence of furfural.

Amino-carboxylic acids may be added at any stage before the conversion of the resin to its final form. The amino acid may be formed *in situ* as for example by the action of chloroacetic acid on aniline. Blue-colored resins of improved mechanical and electrical properties are formed.<sup>40</sup>

Harder and more water-resistant glycerol phthalate resins are prepared by treatment with ketene. The free hydroxyl groups in the glycerol phthalate resin are acetylated under these conditions.<sup>41</sup> Glycerol, 29.7 parts, is heated with 70.3 parts of phthalic anhydride for 4 hours at 200°C. until the resin has an acid value

<sup>41</sup> German P. 533,164, 1933, to Allgemeine Elektrizitäts-Ges.; *Chem. Abs.*, 1934, 28, 363. The neutral product may in turn be further polymerized by heating. See German P. 533,924, 1934, to Degussa A.-G. (Anorgewerkstoff); *Chem. Abs.*, 1934, 28, 3607.

<sup>42</sup> For the treatment of glycerol phthalate resins with monobasic acids see Chapters 43 and 44.

of 120-130. Ketene ( $\text{CH}_2=\text{C}=\text{O}$ ) is then passed through a 50 per cent acetone solution of the resin, the temperature being maintained at  $50^\circ\text{C}$ . until the exothermic reaction is complete. The product thus formed is darker in color and has a higher acid number than the original resin but is more resistant to water. The ketene-treated resin is compatible with nitrocellulose.<sup>42</sup>

A great many other modifying agents may be combined in the resin molecule for the same purpose or to produce resins of different properties. Such chemically modified resins are the subject of the chapters immediately following.

#### OTHER POLYBASIC ACIDS

Of the aromatic polybasic acids, other than phthalic,<sup>43</sup> Downs and Weisberg<sup>44</sup> suggested diphenic and 1,8-naphthalic acids. These aromatic acids are not as easily available as phthalic (see Fig. 126) and, when an acid other than phthalic is to be used, it may be selected from the aliphatic polybasic acids (succinic, maleic, fumaric, malic, malomalic, citric, aconitic, adipic, azelaic, sebacic, diglycolic and thiodiglycolic acids).<sup>45</sup>

Halogenated acids (tetrachlorophthalic anhydride,<sup>46</sup> chlorosuccinic, chloromalic and halogenated fumaric and sebacic acids)<sup>47</sup> have also been recommended. Other types are aromatic ketone-acids and the condensation products obtained when maleic anhydride reacts with either vinyl acetate or styrene. Examples of simple polyhydric alcohol resins, made from these acids, will now be described.

<sup>46</sup> G. Walter, *Monatsh.*, 1934, 64, 287; *Chem. Abs.*, 1935, 29, 153. The tetrachlorophthalic acid was prepared by the action of chlorosulphonic acid on naphthalene.

<sup>47</sup> F. Zwillgmeier, U. S. P. 1,950,468, Mar. 13, 1934, to National Aniline & Chem. Co.; *Chem. Abs.*, 1934, 28, 3255.

<sup>56</sup> Certain of the carbonic esters find a use. The  $\beta,\beta$ -dialkoxyethyl carbonates, either the methoxy or the ethoxy, may be employed as plasticizers for cellulose acetate. See H. B. Smith, U. S. P. 1,905,518.

**Succinic Acid.**  $(\text{HOOC}-(\text{CH}_2)_2-\text{COOH})$ .<sup>17</sup> A product called succinin was obtained by van Bemmelen<sup>18</sup> on heating equal weights of succinic acid and glycerol to 130°C. More glycerol was thus present than corresponded to the acid equivalent. The product was a thick syrup and when heated to 200-220°C. for several hours the mass became hard and tough, losing all acid taste. The resinous material was of a brownish black color, insoluble in water, alcohol, ether or carbon disulphide. When boiled with alcohol and water it slowly decomposed, forming a syrupy substance. The resin likewise dissolved on treatment with caustic alkali solutions or with a suspension of lead oxide. On heating one equivalent each of succinic and benzoic acids and somewhat more than one equivalent of glycerol, water was driven off at about 100° and at 140°C. benzoic acid began to sublime. Additional quantities of benzoic acid were added and the mixture was heated to 200°C. for several hours until sublimation no longer took place. When hot the product was a viscous black mass, cooling to a tough elastic substance which could be drawn into threads. It was insoluble in alcohol, ether and water but decomposed slowly on boiling with water. It dissolved readily in hot alkaline solutions. Van Bemmelen observed that succinic acid combined quickly with the glycerol whereas benzoic acid combined later and with less readiness. The product was called benzosuccinin. Funaro and Danesi<sup>19</sup> also prepared succinin according to van Bemmelen's method by heating succinic acid and glycerol to 200°C. The product was dissolved in boiling water, treated with animal charcoal and filtered while hot. On cooling, succinin separated as a colorless semi-solid mass.

Van Bemmelen<sup>18</sup> obtained a water-soluble syrup by heating equivalent proportions of succinic acid and mannite to 170°C. Cane sugar and succinic acid at 160°C. yielded a humus-like substance.

As a result of a series of investigations Callahan<sup>20</sup> concluded that 2 parts of succinic acid to 1 part of glycerol yielded the most satisfactory product. A greater proportion of acid renders the product too hard; less acid results in a soft sticky resin. For succinic acid the temperature of treatment is 200°C. The time of heating depends somewhat on the size of the batch, from 15 minutes to 3 hours being required. A solution of the soluble resin in acetone may be used as a varnish.

The resin from succinic acid and glycerol is tough and flexible whereas that from phthalic anhydride and glycerol is hard and has a tendency toward brittleness according to Callahan.<sup>20</sup> By combining succinic acid and phthalic anhydride with glycerol it was found possible to make a tougher resin than that from phthalic anhydride alone. When a mixture of 118.4 parts of phthalic anhydride (4/5 mol), 141.5 parts succinic acid (1 1/5 mols) and 184 parts glycerol is heated, the first stage is the formation of a viscous, acetone-soluble resin. Further heating causes it to become insoluble and infusible. If the temperature is too high in the final heating a vesiculated mass is formed, but at lower temperatures (85-150°C.) no bubbles appear and the resin is clear. A layer 1/10 inch thick be-

comes insoluble in 10 hours at 150°C. and forms a very tough product. Glycol succinate has been used in laminated glass.<sup>62</sup>

Arsem<sup>63</sup> made a mixed phthalic-succinic resin. He first prepared an intermediate resin from 1 mol of phthalic anhydride and 1 mol of glycerol and then combined succinic acid with this hydroxy-ester. A mixture of 184 parts of glycerol and 296 parts of phthalic anhydride is first heated at 200-210°C. until gas bubbles cease and 118 parts of succinic are then added to combine with the basic resin. The mixture finally is heated at 210-225°C. until it becomes jelly-like and, when cold, forms a brittle, hard, transparent mass. Arsem believed that this resin is not identical with one formed by heating a mixture of all three reactants in one step.

Downs and Weisberg<sup>64</sup> produced mixed resins containing succinic and malic, tartaric, maleic or fumaric acids. Like phthalic resins, these also exist in three forms: soluble (A), partially soluble-fusible (B) and insoluble, infusible, and water-resistant (C). To obtain the resin in the final form, the reacting materials are heated between 170° and 200°C. for about 20 hours, then below 135°C. for 10 hours or until the stage is passed where bubbles form in the resin, and finally the temperature is raised as high as 250°C. until the resin is water-resistant.

By the reaction between silver succinate and ethylene dibromide, Vorländer<sup>65</sup> obtained a microcrystalline powder which he considered to be the dimer of ethylene succinate. However, Carothers and Arvin<sup>66</sup> found the molecular weight of the material to vary between 1400 and 2000. The succinic ester of ethylene glycol may be prepared in various degrees of polymerization. These esters have been investigated by Carothers and Dorough,<sup>67</sup> who found that when prepared by the general method of heating the glycol and acid the products contained the group

to an extent varying between 6 and 23 structural units per molecule. These polymers are soluble in chloroform but insoluble in ether and benzene. The lower polymers are soluble in water. A still lower polymer, probably the dimer, was obtained by Tilicheiev<sup>68</sup> by distilling the higher polymers. The monomer is not known to exist.

Carothers and Hill<sup>69</sup> heated a sample of polyethylene succinate in a high vacuum and obtained a tough, horny, somewhat elastic residue. On heating to 97°C., it softened to a very viscous, slightly rubbery mass which could be drawn out into fibers. With excess glycol at 100°C. succinic acid forms the di-β-hydroxy-ethyl succinate,

The diacetyl derivative boils at 198° at 5 mm.

**Malic Acid.** Callahan<sup>72</sup> used malic acid and glycerol to produce a resin which could be used for molded insulation, or mixed with harder resins (phthalic glyceride) to make them tougher. In his process 134 parts malic acid and 92 parts glycerol are heated first to 110°C., ebullition occurs and the temperature is then raised gradually to 235°C., yielding a flexible and somewhat sticky resin. It is soluble in acetone and is fusible at approximately 100°C. Heating for a period of about 15 hours at a temperature below the fusing point but rising to 100°C. yields an infusible resin.

Protracted heat treatment is necessary if the resin from malic acid and glycerol is to be resistant to water. Downs and Weisberg<sup>73</sup> found that this resin and mixed resins containing malic and other dibasic acids could be rendered water-resistant to such an extent that a test sample submerged in boiling water for two minutes does not turn white. Heating the resin for about 30 hours at 170°C. is necessary.

Edible resins for use in making grease-proof wrapping paper for foodstuffs or as chicle substitutes in chewing-gum compositions are obtained from fruit acids such as malic or citric.<sup>74</sup> For example a mixture of 101 parts malic acid, 42 parts diethylene glycol and 24 parts glycerol is heated at 220-240°C., finally yielding a semi-elastic gel.

When malic acid is heated at 100°C. in air or in a vacuum, tribasic malomalic acid is formed from two molecules of malic acid. After fusing, the cold melt has a glass-like appearance.<sup>74</sup> Downs and Weisberg<sup>75</sup> have suggested the use of this acid in resins.

**Tartaric Acid.** In 1847 Berzelius,<sup>76</sup> on heating glycerol and tartaric acid to 150°C., obtained a soft mass which could be drawn out into threads. The product was deliquescent and could easily be hydrolyzed by water. Desplats<sup>77</sup> also studied the reaction between glycerol and tartaric acid.<sup>78</sup>

**Maleic and Fumaric Acids.**<sup>79</sup> Weisberg and Potter<sup>80</sup> heated maleic acid in the proportion of one mol of glycerol to one of acid. The acid dissolves forming a homogeneous mass and, as the heating is continued, the melting point gradually rises and the material, which at first is quite sticky and viscous, eventually loses its stickiness and becomes more solid when cold. At this stage the product is soluble in acetone, making a clear solution useful as a varnish. The time required to reach this point may vary according to the temperature at which the

heating is conducted, the bulk of the batch and the rate of stirring. This resin is also soluble at room temperature in ethyl alcohol and ethyl acetate but less so than in acetone. It dissolves slightly in benzene. Cold water acts on it rapidly, causing it to become discolored and soft. If heating is continued at about 200°C., an exothermic reaction occurs with frothing, and the material becomes filled with bubbles. This frothy product may be rendered homogeneous by grinding and molding under heat and pressure. A bubble-free product may be obtained directly, however, by heating at a temperature at or near the melting point of the A-stage resin; the maximum temperature below 135°C. and may be as low as 90°C. or lower. For example, a batch of two pounds may be converted at 135°C. in about ten hours from the A-stage resin to the B-stage. This B-stage resin is insoluble in acetone, ethyl alcohol, and ethyl acetate, but on standing in contact with any of these materials for a considerable time, the finely powdered resin swells and forms a jelly-like mass. Heated for about 30 hours longer the resin reaches the C-stage.

On attempting the preparation of ethylene fumarate and maleate the formation of resins was observed by Vorländer.<sup>81</sup> Silver fumarate gave with ethylene dibromide a crystalline, apparently polymeric product which was transformed on heating into a transparent, infusible and very insoluble glass. The original "ethylene fumarate" was slowly dissolved by alkali, and added on bromine to give polymeric ethylene dibromosuccinate as a gummy mass, solidifying to an amorphous substance. From silver maleate with ethylene dibromide the corresponding ester was also obtained as a viscous gum, solidifying to a glass at low temperatures. Heated at 150-160°C. it was transformed into a rubber-like substance.

Vorländer likewise obtained resinous products on removal of chlorine from di(chloroethyl) fumarate,

by silver.

Fumaric acid also forms resins with polyhydric alcohols.<sup>82</sup> This acid behaves very much like maleic in its reaction with glycerol except that having a higher melting point, the first step is usually carried out at a higher temperature.

Zwilmeyer<sup>83</sup> has made use of halogenated acids in the preparation of the alkyd resins. The method of carrying out the preparation is as follows: a mixture of 183 parts of glycerol and 355 parts of monobromo-maleic anhydride

is slowly heated with stirring while a general increase in viscosity takes place. When gas evolution ceases, 430 parts of the mono-isopropyl ester of monochloro-succinic acid,

<sup>81</sup> D. Vorländer, *Ann.*, 1894, 280, 171; *Chem. Zentr.*, 1894, 2, 657; Beilstein, 4th Ed., 1920, II, 752.

are added. The resulting mixture is heated to 180-290°C. to yield a resinous material of very high elasticity. The mono-isopropyl ester of monochlorosuccinic acid is prepared by heating maleic anhydride and isopropyl alcohol in the presence of hydrogen chloride and separating with alkali the mono-acid salt.

In place of the mono-isopropyl chlorosuccinate, 145 parts of acrylic acid may be added<sup>84</sup> and the mixture heated to 180-200°C. to produce a hard, brittle resin soluble in acetone and in diethyl phthalate.

**Citric Acid.** Experiments by van Bemmelen<sup>85</sup> yielded a product which he termed citrin. One equivalent of citric acid heated at 160°C. with an excess of glycerol yielded a syrupy product which after several hours heating at 160-170°C. became very hard, tough, brownish-yellow, porous and difficult to pulverize. Even at 200°C. the material exhibited approximately the same consistency as at room temperature. On exposure to air the sample grew softer. It was insoluble in water, alcohol and ether and when allowed to stand in cold water for a long time produced no acid reaction. When boiled with alcohol and water it became a thick syrup. One equivalent of citric acid with approximately two equivalents of glycerol heated for several hours to 170°C. yielded citro-diglycerol. One equivalent each of citric acid and glycerol heated for 20 hours at 160°C. yielded a very hard, light yellow, transparent resin, which adhered tenaciously to the glass of the vessel in which it had been prepared and could not readily be separated. This was much harder than citro-diglycerol and did not soften in the air. In hot and cold water very little action was noticed. It was soluble in concentrated hydrochloric acid and dissolved in sulphuric acid with blackening. Van Bemmelen considered this product to be citro-monoglycerol. He summarized the reaction between citric acid and glycerol in this manner: at 100-120°C. a syrup is formed and water is evolved, between 100-200°C. the syrup grows thicker and, after longer heating and the loss of 4 to 6 equivalents of water, this changes to a solid neutral insoluble substance.

Lourenço<sup>86</sup> heated citric acid and glycerol to 160°C. obtaining a gummy, water-soluble body. Heating to 215°C. resulted in a hard, brittle product, insoluble in water. At 140°C. equivalent quantities of mannite and citric acid yielded a hard yellowish, tasteless substance insoluble in water, alcohol or ether.<sup>87</sup>

Callahan,<sup>88</sup> on heating 1.5 parts of citric acid and 1 part of glycerol at a temperature of 160°C., formed a resin which was hard and strong but which did not have the flexibility desired for impregnating paper or cloth for electrical insulation. The addition of certain substances, specifically, meta-dinitrobenzene, ethyl benzoate, acetanilide and  $\beta$ -naphthol, promotes flexibility of the citric acid resin according to Dawson.<sup>89</sup> To a mixture of 11.4 parts of citric acid, 5 parts of glycerol and 5 parts of methyl alcohol are added from 1 to 10 parts of the plas-

ticizing agent. Articles to be impregnated are dipped into the solution and baked at 125°C. to drive out the alcohol and to start the reaction which is completed at 150-200°C. The resin obtained from citric acid and glycerol at low temperature lacks water-resistance. Reaction at high temperature (180-200°C.) lessens the hygroscopicity of the product but at the same time causes a deepening in the color. By adding an appropriate dye (methyl violet 2B)<sup>90</sup> to the resin before it becomes infusible and insoluble, a colored product is first obtained. On heat treatment, the color developed during resin-decomposition is neutralized by the dye and a water-white product results. The proportions of the various constituents used are as follows: 200 g. of citric acid (crystals), 100 g. of glycerol and 8 cc. of a 0.1 per cent aqueous solution of methyl violet 2B.<sup>91</sup>

The product obtained by treating citric glyceride with acetic or benzoic anhydride is water-soluble. A mixture of glycerol and aconitic acid forms an elastic resin.<sup>92</sup>

Sager<sup>93</sup> recommended as a ground-joint lubricant the resin obtained by heating 1 mol of citric acid and 1.5 mols tetraethylene glycol at 180°C. for 1.5 hours. It is insoluble in both aromatic and aliphatic hydrocarbons but is soluble in water, alcohol and acetone.

**Adipic Acid.**  $\text{HOOC}(\text{CH}_2)_4\text{COOH}$ . A process for making adipic acid and its homologues consists in the oxidation of hydroaromatic alcohols produced by the hydrogenation of phenols. The oxidation may be carried out with nitric acid in the presence of an oxidizing catalyst (vanadium or molybdenum oxide or compounds such as ammonium vanadate)<sup>94</sup> at a temperature of 50-60°C. Homologues may also be obtained by this means:  $\alpha,\beta$ -dimethyl adipic acid (2,3-dimethyl hexanedioic acid) is produced by oxidizing 1,3,5-hexahydro-xylenol.<sup>95</sup>

The adipic esters can be used as softening agents in the celluloid, lacquer, and film industries.<sup>96</sup> Heating the esters of adipic acid with polyhydric alcohols yields gum-like, hard products, which have been suggested as rubber substitutes.<sup>97</sup>

Differing from the glycerol-phthalic anhydride resins, which become hard and brittle at high temperatures, those formed from glycerol and adipic acid or other straight-chain dibasic acids (pimelic, suberic, azelaic or sebacic) are permanently soft, rubbery and plastic. There are three stages in their formation, as in other resins of this class. In the A stage they are syrupy liquids, soluble in acetone; in the B stage they are soft and rubbery and soluble in acetone but insoluble in benzene and in the C stage they are soft and rubbery but insoluble in the common organic solvents. One mol glycerol and  $1\frac{1}{2}$  mols adipic acid are heated at 165-170°C. for 1 to 5 hours to yield a resin in the A stage which sets to a firm jelly

<sup>90</sup> Methyl violet 2B has the structure

<sup>96</sup> Esters such as bornyl adipate, cyclohexyl hydrophthalate and cyclohexyl benzoate have also been suggested for use as vulcanization accelerators. (British P. 339,336, 1930, to Deutsche Hydrierwerke A.-G.; *Brit. Chem. Abs. B*, 1931, 264.)

<sup>97</sup> W. Schrauth, *Chem. Ztg.*, 1929, 53, 41; *Brit. Chem. Abs. B*, 1929, 163. See *J.S.C.I.*, 1929, 48, 95.

on cooling. Further heating for  $4\frac{3}{4}$  hours gives the B stage and in a half hour more the C stage.<sup>99</sup>

Synthetic resins are also prepared by condensing adipic acid homologues containing a branched chain with a polyhydric alcohol. These products, which are very plastic and which may be added to phthalic glyceride to produce flexibility, are made by heating a mixture of isomeric methyladipic acids with glycerol and boric acid at  $160^{\circ}\text{C}$ .<sup>100</sup> Vulcanizable mixtures are obtained by adding the elastic, factice-like glycerol ester of methyladipic acid to rubber.<sup>100</sup> When adipic acid is first condensed with triethanolamine it gives an alcohol-soluble product. On further heating this is converted into an insoluble gummy, elastic and gelatinous material which likewise finds use as a softening agent for synthetic and natural resins, and as a vulcanization accelerator.<sup>101</sup>

Adipic esters of the dihydric alcohols form tallowy or butter-like masses. The glycol ester may be prepared by mixing a solution of ethylene glycol and pyridine in pinacolone with a similar solution of the dichloride of adipic acid, or by the action of ethylene dibromide on potassium adipate. The propylene glycol ester is similarly obtained.  $\alpha$ -Methyladipic acid and ethylene oxide react to give a brownish waxy mass.<sup>102</sup> With excess glycol at  $100^{\circ}\text{C}$ . adipic acid forms the di- $\beta$ -hydroxyethyl adipate (b.p.  $210^{\circ}\text{C}$ . at 5 mm.).<sup>102</sup>

**Azelaic Acid.**  $\text{HOOC}(\text{CH}_2)_7\text{COOH}$ . The oxidation of unsaturated oils yields azelaic acid as one of the products. This acid may be condensed with glycerol to form a plastic material<sup>103</sup> recommended for making lacquers or as a binder in linoleum.<sup>103</sup> When azelaic acid is replaced by acids having a longer carbon-chain the products are more flexible.<sup>103</sup>

**Sebacic Acid.**  $\text{HOOC}(\text{CH}_2)_9\text{COOH}$ .<sup>107</sup> Berthelot<sup>108</sup> reacted sebacic acid with glycerol at  $200^{\circ}\text{C}$ . and isolated from the product a small quantity of neutral crystalline compound which he called sebin.

Bruson<sup>109</sup> heated 1 mol of glycerol and 1.5 mol of sebacic acid at  $170^{\circ}\text{C}$ . until a test sample was a firm jelly when cold. At this stage the product is soluble and may be used as a plasticizer for nitrocellulose in coatings for fabrics,<sup>110</sup> or for rubber articles.<sup>111</sup> Further heating renders the mass insoluble but it is still soft and pliant.

The glycol ester was prepared by Carothers and Hill<sup>112</sup> by heating a mixture of sebacic acid and a slight excess of glycol. The product was a hard wax which when softened by heating could be drawn out to transparent fibers.

The resin obtained from sebacic acid and glycerol has been used as a cement

in laminated glass.<sup>114</sup> Resins of this type when used as binders in safety glass have a high holding power. They do not become brittle on exposure to light and maintain their strength and resilience after a long period of use.

With an excess of glycol, sebacic acid reacts at 110-115°C. to yield the di- $\beta$ -hydroxyethyl sebacate of m.p. 46°. On heating to 160°, the ester slowly polymerizes. The diacetyl derivative

boils at 242°C. at 5 mm.<sup>114</sup>

**Camphoric Acid.**  $\text{C}_8\text{H}_{14}(\text{COOH})_2$ . Heated to 200°C. in a sealed tube with glycerol, camphoric acid forms a viscous, neutral mass that Berthelot<sup>115</sup> called camphorin. Callahan<sup>116</sup> also studied its reaction with glycerol. He heated 46 parts of glycerol and 100 parts of camphoric acid to 100°C. whereupon the mixture became uniform in appearance. The temperature was then slowly raised to 250°C. The resinous product is soluble in acetone, slightly soluble in methyl and ethyl alcohol and insoluble in benzene. It is clear, yellow, melts at 110-130°C. and may be hardened by heating for some time at 90-135°C.

#### BORIC ACID

Glycol and glyceryl borates and boriborates are water-soluble resins. They are compatible with nitrocellulose and with gelatin. Glycol boriborate<sup>117</sup> has been used for the lubrication of dyed cotton previous to spinning; it is waxy, hygroscopic, non-corrosive, non-inflammable and water-soluble.<sup>118</sup> By heating to 100°C. 150 parts of diethylene glycol and 70 parts of boric acid together with 80 parts of borax with agitation, combination takes place and, as the temperature is raised from 120-130°C., water is evolved. The resin obtained is a viscous syrup of high molecular weight, tasteless, odorless and of a light amber color or colorless. The resin, moreover, is soluble in water and it is practically neutral, non-corrosive, non-toxic and antiseptic. When heated above 275°C. the product loses water and becomes harder and non-tacky; if heated further, a water-soluble glass is obtained which goes into solution very slowly but which is extremely hygroscopic. It is particularly adaptable as a plasticizer for glues, gelatin, gum arabic, tragacanth or karaya and as a base for cosmetical and pharmaceutical preparations. Dissolved in methyl alcohol or in glycol ethers, it can be used as a special adhesive for glassine, cellophane or celluloid.<sup>119</sup>

The method of refining oils and fats by treatment with anhydrous boric acid<sup>120</sup> has been extended to the use of the boric acid esters of polyhydric alcohols.<sup>121</sup> Moreover, the polyhydric alcohols can be condensed with phthalic anhydride in the presence of boric acid by heating to 250°C. A glycerol-boric ester is used in the preparation of mucilage,<sup>122</sup> and a viscous composition suggested for electrolytic condensers is obtained by the reaction of ethylene glycol with ammonium borate and boric acid.<sup>123</sup>

## ETHER-ACIDS

Resins for moldings or for coatings are formed by the reaction of polyhydric alcohols and ether-carboxylic<sup>124</sup> or thioether-carboxylic<sup>125</sup> acids (diglycolic, methylhydracrylic, salicylacetic, thiodiglycolic, thiodilactylic and 2-carboxyphenylthioglycolic acids or anhydrides). For example, diglycolic acid, heated with glycerol to a final temperature of about 140°C., yields a colorless product having the consistency of honey, which on heating in a thin layer at 160°C. for several hours gives a solid film. These hardened condensation products are good electrical insulators and are very elastic and pliable. They are recommended as coatings for wire, wire fabrics<sup>126</sup> and other metallic parts<sup>127</sup> of electrical machinery, or they can be mixed with fibrous fillers and molded under pressure.<sup>128</sup>

## KETONE-ACIDS

Acids of this class, which have been used to form resins by reaction with polyhydric alcohols, include benzoylbenzoic, toluylbenzoic, and benzophenone-2,4'-dicarboxylic acids.

Downs and Weisberg<sup>129</sup> heated benzoylbenzoic acid with glycerol to produce a hard resin unaffected by water. Polybasic acids may replace part of the benzoylbenzoic acid. Ellis<sup>130</sup> found that a mixture of 120 parts of toluylbenzoic acid and 15.5 parts of glycerol, heated for half an hour to a temperature of 290°C. in an aluminum vessel equipped with a short air-cooled condenser, yields a hard resin of acid number 23.4. This resin is compatible with cellulose acetate. Benzoylbenzoic acid treated in the same way yields a resin whose acid number is 19.3.

Hahn<sup>131</sup> incorporated benzoylbenzoic glyceride with cellulose acetate in a lacquer. One formula suggested is 12 parts of cellulose acetate, 3 parts resin, 6 parts of softener and 79 parts of solvent.<sup>132</sup> Other esters of benzoylbenzoic acid (propyl, butyl, isoamyl) have been suggested as plasticizers for cellulose nitrate and acetate.<sup>133</sup>

Benzoylbenzoic, toluylbenzoic, chlorbenzoylbenzoic and similar acids, formed by the action of aromatic hydrocarbons or hydrocarbon derivatives on phthalic anhydride in the presence of aluminum chloride, are monobasic acids. The resins obtained by their reaction with glycerol can hardly be considered to have the complexity of the resins formed from dibasic acids. It is even doubtful if they

<sup>132</sup> A. O. Jaeger used the alkyl esters of acids of this type, such as butyl benzoylbenzoate, methyl benzoylacrylate and butyl naphthoylbenzoate as plasticizers for resins. See A. O. Jaeger, U. S. P. 1,978,710, Oct. 30, 1934, to American Cyanamid & Chemicals Corp.; *Chem. Abs.*, 1935, 29, 253. French P. 703,018, 1930, to Selden Co.; *Chem. Abs.*, 1931, 25, 4423. British P. 359,164, 1929; *Chem. Abs.*, 1932, 26, 4969. H. J. West (U. S. P. 1,809,614, June 9, 1931, to Selden Co.; *Chem. Abs.*, 1931, 25, 4828) recommended butyl benzoylbenzoate for use in high-vacuum pumps.

<sup>133</sup> H. A. Bruson, U. S. P. 1,909,092, May 16, 1933, to American Cyanamid Co.; *Brit. Chem. Abs. B*, 1934, 37.

can be considered polymeric in the same sense. Their resinous nature is more probably the result of their slowness of crystallization. Toluylbenzoic acid can be fused to form a melt which remains glassy for a long time.<sup>134</sup>

Benzophenone-2,4'-dicarboxylic acid is insoluble in water and does not sublime when heated, properties of importance in resin production. Resins made from this acid are resistant to water and no loss of acid occurs in their formation. Bruson<sup>135</sup> heated a mixture of 270 parts benzophenonedicarboxylic acid and 62 parts glycerol in a kettle equipped with an agitator and after heating for about 5 hours at 190-200°C., obtained a hard resin readily soluble in acetone. After 8 or 10 hours at this temperature the resin reverts into an insoluble and infusible form. Ethylene glycol and benzophenone-2,4'-dicarboxylic acid yield a hard, brittle, pale resin soluble in butyl acetate or acetone. If pentaerythritol is used, the resin becomes insoluble and infusible after only 3 or 4 hours at 180-190°C.

Another group of polybasic acids includes the products obtained by treating maleic anhydride with compounds containing conjugated double bonds and capable of forming simple adducts according to the diene synthesis.<sup>136</sup>

Such compounds as vinyl acetate, styrene, indene and acrylic esters react with maleic anhydride when heated in the presence of a catalyst like benzoyl peroxide to form polymeric polybasic acids.<sup>137</sup> These products may be heated with glycerol to yield resins or the glycerol may be added before polymerization.<sup>138</sup> For example, a mixture of styrene, maleic anhydride and glycerol, heated in an autoclave to 120°C., yields a resin insoluble in alkalis or in organic solvents.

#### POLYHYDRIC ALCOHOLS

Being the most generally available polyhydric alcohol, glycerol has been more widely used than any other alcohol of this type to form resins by reaction with polybasic acids. In certain instances the glycerol is replaced by an acid glyceride such as triacetin. The acid under these conditions is volatilized at the temperature of the reaction.<sup>139</sup>

Other alcohols than glycerol include polyglycerol, the glycols and polyglycols, pentaerythritol, sorbitol<sup>140</sup> and mannitol. Different polyhydric alcohols usually yield different products with the same polybasic acid. When heated for a sufficiently long time with either a dibasic acid or a more highly carboxylated compound, glycerol forms an insoluble, infusible mass. Polyhydric alcohols containing more than three hydroxyl groups form this kind of material even more readily than glycerol. On the other hand glycols (containing only two hydroxyl groups) react with dibasic acids to form permanently fusible bodies, but with acids containing more than two carboxyl groups they may be expected to yield insoluble bodies. The complexity of the reactants thus forms the basis for classifying sim-

<sup>134</sup> Cf. Chapter 4, especially the work of D. Vorländer.

<sup>135</sup> H. A. Bruson, U. S. P. 1,813,838, July 7, 1931, to Röhm & Haas Co.; *Chem. Abs.*, 1931, 25, 5305. U. S. P. 1,807,503, May 26, 1931; *Chem. Abs.*, 1931, 25, 4139. See German P. 562,954, 1933, to Chem. Fabr. Kurt Albert G.m.b.H.; *Chem. Abs.*, 1934, 28, 919.

<sup>140</sup> H. H. Strain (*J.A.C.S.*, 1934, 56, 1756) has found that the rare sugar alcohol d-sorbitol occurs in large quantities (2.4-2.7 per cent) in Toyon berries (the fruits of *Photinia arbutifolia*, Lindl.) and may be isolated by extraction with boiling water or with ethanol, followed by fermentation and recrystallization. When ethanol is used, fermentation apparently is not necessary and the sorbitol may be directly recrystallized from pyridine.

ple polyhydric alcohol-polybasic acid resins into heat-convertible and heat-non-convertible resins as proposed by Kienle and Ferguson.<sup>141</sup>

#### POLYGLYCEROL

Polyhydric alcohols generally can be condensed with themselves to yield complex bodies retaining an alcoholic character.<sup>142</sup> When glycerol is distilled the residue in the still contains di- and triglycerol, the mixture being called "polyglycerols."<sup>143</sup> They are formed by the elimination of water between two or more molecules of glycerol. By heating glycerol for a half hour at 280°C. in the presence of 0.5 per cent of sodium hydroxide (or acetate) the greater part of the glycerol is converted into the condensation product. This condensed glycerol reacts more rapidly with organic acids than normal glycerol and its use facilitates resinification. The initial fusible or class A resin is formed in about one-fifth the time required

<sup>141</sup> R. H. Kienle and C. S. Ferguson, *Ind. Eng. Chem.*, 1929, 21, 349. See also R. H. Kienle, *ibid.*, 1930, 22, 590. See Chapter 41.

<sup>142</sup> The formation of polyglycerols is discussed by E. Leurs (*J.S.C.I.*, 1922, 41, 97T), by A. Rayner (*ibid.*, 224T) and by M. Rangier (*Compt. rend.*, 1923, 187, 345; *Chem. Abs.*, 1923, 22, 4458). R. I. Bashford heats glycerol with zinc chloride (U. S. P. 1,467,299, Sept. 11, 1923, to Grasselli Powder Co.; *Chem. Abs.*, 1923, 17, 3680). Diglycerol is obtained by heating glycerol with thorium or magnesium oxide and with or without sodium silicate (British P. 265,146 and 265,147, 1926, to Henkel & Cie. G.m.b.H.; *Chem. Abs.*, 1926, 22, 244. H. Weber and F. Niemeyer, German P. 494,430 and 494,431, 1926, to Henkel & Cie. G.m.b.H.; *Chem. Abs.*, 1930, 24, 3760). Passing inert gases through glycerol which is heated with sodium acetate yields diglycerol. (British P. 264,800, 1926, to Henkel & Cie. G.m.b.H.; *Chem. Abs.*, 1926, 22, 244.) S. N. Ushakov and E. M. Obryadina, *Plast. Massui*, 1932, (1) 19; *Chimie et industrie*, 1933, 29, 1418; *Chem. Abs.*, 1933, 27, 4426; *Ind. Eng. Chem.*, 1933, 25, 997, state the most efficient catalysts for direct polymerisation of glycerol by heat are sulphuric acid, sulphurous acid, sulphates and sulphites, particularly mercuric and cupric sulphates. By refluxing glycerol for 4 hours in the presence of 4 per cent catalyst, condensation occurs to the extent of 60-68 per cent. The product is dark-brown, viscous and soluble in water, alcohol, acetone and in alcoholic benzene. Further heating results in an infusible material which can form elastic films. Purification by steam distillation yields 31-50 per cent of a dark brown secondary resin which is insoluble in water and corresponds to the structural formula  $(\text{C}_3\text{H}_5\text{O}_2)_n$ . See Chapters 24 and 50.

<sup>143</sup> For the cyclic ethers formed by autocondensation of glycerol and their use as plasticisers for cellulose derivatives, see H. Dreyfus, French P. 745,040, 1933; *Chem. Abs.*, 1933, 27, 4428. O. Mers (*Farben-Chem.*, 1934, 5, 91; *Brit. Chem. Abs. B*, 1934, 616) has considered the glycerol ethers as solvents, especially their miscibility with common varnish solvents and thinners, the solvent power for nitro-cellulose, for acetyl cellulose and for natural and synthetic resins. For the action of heat and glycerol on nitrocellulose and for the manner in which the viscosity of the latter is lowered, see M. G. Milliken, U. S. P. 1,967,180, May 1, 1934, to Hercules Powder Co.; *Chem. Abs.*, 1934, 28, 4231.

with glycerol. The physical properties of the polyglycerol resins do not differ greatly from those made from normal glycerol.<sup>144</sup>

## GLYCOLS

When equimolecular amounts of phthalic anhydride and ethylene glycol are heated together to 140-160°C., the monoester

is first formed by direct addition of the reactants. This compound can be obtained in the form of crystals. Further heating causes an increase in the molecular weight by union of a large number of molecules of the initial simple ester. The viscosity of the heated mass increases but the product remains fusible at all stages.<sup>145</sup> It is compatible with both nitrocellulose and cellulose acetate.<sup>146</sup> Glycol-phthalic anhydride resin has been recommended as a cement for high-vacuum work<sup>147</sup> and has been suggested for impregnating paper and for the manufacture of lacquers.<sup>148</sup> The ethylene glycol phthalate can be prepared by using as catalysts such substances as sulphuric acid,<sup>149</sup> basic cuprous carbonate, bismuth subcarbonate, the carbonates of cobalt, lithium, manganese, cadmium and barium, and the nitrates of calcium, beryllium,

<sup>144</sup> See L. Weisberg and R. S. Potter, U. S. P. 1,424,137, July 25, 1922, to the Barrett Co.; *Chem. Abs.*, 1922, 16, 3219. See also F. Groff, U. S. P. 2,008,417, July 16, 1935, to Bakelite Corp.

<sup>145</sup> H. Hönel, *Kunststoffe*, 1931, 35, 76, 105, 132; *Chem. Abs.*, 1931, 25, 5047.

<sup>146</sup> H. E. Hofmann and E. W. Reid, *Ind. Eng. Chem.*, 1929, 21, 964. The soft nature of the esters of glycol and polyglycols makes them valuable as plasticizers for cellulose esters. O. Loehr reacts polyglycols with benzoic acid and obtains a high-boiling viscous liquid which he mixes with cellulose nitrate or acetate to form flexible lacquers. (U. S. P. 1,783,176, Dec. 2, 1930, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1931, 25, 414. Canadian P. 285,919, 1923; *Chem. Abs.*, 1929, 23, 1267.) O. Loehr also uses the benzoates of polyethylene glycol monoethyl ethers (U. S. P. 1,865,196, June 28, 1932, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1932, 26, 4487). Such mixed esters of diethylene glycol as the butyrate-laurate have been suggested for the same purpose (R. Calvert, U. S. P. 1,807,304, May 26, 1931, to Van Schaack Bros. Chemical Works, Inc.; *Chem. Abs.*, 1931, 25, 4090). Other phthalic esters which have been mentioned for use as cellulose ester plasticizers are: dibenzyl phthalate (R. H. Van Schaack, Jr., U. S. P. 1,734,657, Nov. 5, 1929, to Van Schaack Bros. Chemical Works, Inc.; *Chem. Abs.*, 1930, 24, 515) phenoxy phthalate (R. L. Kramer, British P. 306,911, 1928, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1929, 23, 5338), the phthalate of methyl salicylate (L. P. Kyrides, U. S. P. 1,979,559, Nov. 6, 1934, to Monsanto Chemicals Corp.; *Chem. Abs.*, 1935, 29, 177. British P. 421,420, 1933; *Brit. Chem. Abs. B*, 1935, 194),  $\beta$ -acetoxyethyl butyl phthalate (H. D. Young, U. S. P. 1,786,404, Dec. 28, 1930; *Chem. Abs.*, 1931, 25, 610) and di-( $\beta$ -methoxyethyl) phthalate (British P. 279,771, 1926, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1928, 22, 3044). On the preparation of  $\beta$ -methoxyethyl benzoate see R. C. Conn, A. R. Collett, and C. L. Lassell (*J.A.C.S.*, 1932, 54, 4371). R. H. Van Schaack, Jr., and R. Calvert make a plasticizer by acetylating di-( $\beta$ -hydroxyethyl) phthalate (U. S. P. 1,733,639, Oct. 29, 1929, to Van Schaack Bros. Chem. Works, Inc.; *Chem. Abs.*, 1930, 24, 379). They also recommend compounds like hydroxyethyl ethyl phthalate as high-boiling solvents and plasticizers (R. H. Van Schaack, Jr., and R. Calvert, U. S. P. 1,706,639, Mar. 26, 1929, to Van Schaack Bros. Chem. Works, Inc.; *Brit. Chem. Abs. B*, 1929, 636); also ethylene glycol phthalates or mixed esters of bis- $\beta$ -hydroxyethyl phthalate (R. H. Van Schaack, Jr., and R. Calvert, U. S. P. 1,922,646, May 8, 1933, to Van Schaack Bros. Chem. Works, Inc.; *Brit. Chem. Abs. B*, 1934, 546. J. M. Kessler and O. B. Helfrich form the phthalic esters of polyglycol monoalkyl ethers; for example, the phthalate of diethylene glycol monoethyl ether (U. S. P. 1,714,173, May 31, 1929, to Kessler Chemical Co.; *Chem. Abs.*, 1929, 23, 3583). The esters formed from saturated fatty acids and the ethylene glycol monoalkyl ethers also serve as plasticizers for cellulose esters (J. R. Buckley, U. S. P. 1,869,660, Aug. 2, 1932, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1932, 26, 5310). The esters of saturated acids, such as stearic, and ethers of diethylene glycol have been suggested (J. M. Kessler and O. B. Helfrich, U. S. P. 1,739,315, Dec. 10, 1929; *Chem. Abs.*, 1930, 24, 862).  $\beta$ -Butoxyethyl- $\beta$ -hydroxyethyl phthalate formed by esterifying glycol with phthalic acid and subsequent esterification with  $\beta$ -butoxyethanol, or vice versa, and compounds of this general structure have a high solvent power for plastics in general (R. B. Fraser, British P. 410,797, 1934, to Carbide & Carbon Chemicals Corp.; *Chem. Abs.*, 1934, 28, 6443. French P. 746,467, 1933; *Chem. Abs.*, 1933, 27, 4539. See also H. Dreyfus, British P. 418,506, 1934; *Chem. Abs.*, 1935, 29, 2200.) This also applies to the esters of monoalkyl ethers of the polyglycols (E. F. Isard, U. S. P. 1,943,979, Jan. 16, 1934, to E. I. du Pont de Nemours & Co.; *Brit. Chem. Abs. B*, 1934, 932). H. Dreyfus (British P. 420,221, 1933; *Brit. Chem. Abs. B*, 1935, 161) prepared cyclic monomeric esters by reacting ethylene glycol with phthalic anhydride in the presence of 0.5 per cent of orthophosphoric acid at 135°C. or by heating sodium  $\beta$ -chloroethyl phthalate at 150°C. and by treating  $\alpha$ -dicarbethoxyethylene and  $\beta\beta'$ -iminodiethyl phthalate. For alkoxyalkyl esters of long-chain dibasic acids see E. F. Isard, U. S. P. 1,991,891, Feb. 19, 1935, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1935, 29, 3176.

lithium<sup>120</sup> and copper.<sup>121</sup> The presence of metallic compounds stabilizes the products against the destructive influences of light.

Ethylene glycol boils at a lower temperature (197°C.) than glycerol and when it is used to form a resin the reaction will be carried out at a lower temperature. The polyglycols or dihydroxy ethers, however, have fairly high boiling points. Of these, diethylene glycol has been used most widely. Gardner, Knauss and Van Heuckeroth<sup>122</sup> have used triethylene glycol. They heated equimolecular proportions of phthalic anhydride, triethylene glycol, and tartaric acid at 185-200°C. for 3 hours and obtained a pale amber viscous liquid resin, soluble in acetone, alcohol, and chloroform, insoluble in toluene, and compatible with nitrocellulose solutions. When heated for 15 to 18 hours this product becomes a dark amber plastic mass incompatible with nitrocellulose but compatible with cellulose acetate solutions. Exposure tests of lacquers containing equal parts of the dark resin and cellulose acetate gave fairly satisfactory results.

Glycol condenses with glutaric acid in the presence of zinc chloride at 135-140° to give a gummy acid ester.<sup>123</sup> The degree of polymerization of this ester is apparently less than in the succinic acid series and corresponds to the formula

1,3-Butylene glycol, when heated with phthalic anhydride to 160°C., gives a glassy product;<sup>124</sup> with maleic anhydride reaction also takes place.<sup>125</sup>

When the same glycol is heated to 100° with adipic acid, butyl alcohol and concentrated phosphoric acid, it yields a thick oil.<sup>126</sup>

Bradley<sup>127</sup> used glycols such as propane-1,2-diol, trimethylene glycol and 2,3-butyleneglycol. These react with phthalic anhydride to yield resins which are more soluble than those from glycerol. The resins from the first two glycols mentioned are partially soluble, and that from the third, completely soluble in toluene. A mixture containing one mol each of propane-1,2-diol and phthalic anhydride is heated in a partially closed vessel to 290°C. for approximately 2.5 hours. The product is a soft, straw-colored resin (acid number about 56). These resins improve gloss and adhesion when added to nitrocellulose lacquers.

Polyglycols are formed by heating ethylene glycol or by polymerizing ethylene oxide. The alkylene oxides themselves form various light-colored, viscous products when treated with polybasic acids. For example, water-soluble esters are produced by treating 1 mol of phthalic anhydride with 2 mols of ethylene oxide. The reaction is carried out in the presence of a small amount of sodium phthalate in an autoclave heated to 60-65°C. The product is a viscous liquid.<sup>128</sup> Succinic acid and ethylene oxide, heated in an autoclave at 80-90°C., also yield a viscous, water-soluble product.<sup>129</sup> Tetraethylene glycol,  $\text{HOCH}_2-(\text{CH}_2\text{OCH}_2)_3-\text{CH}_2\text{OH}$ ,

can be prepared from ethylene oxide and triethylene glycol by a pressure reaction.<sup>100</sup>

Glycerol  $\beta$ -hydroxyethyl ether is formed by treating glycerol with ethylene oxide at an elevated temperature.<sup>101</sup> Heated with phthalic anhydride this com-

TABLE 45.—Oxides.

pound forms a soft mass which may be used as a plasticizer. With succinic acid the ether yields a viscous product which hardens on further heating to an insoluble, elastic resin. Sorbitol hydroxyethyl ethers are obtained in the same way and can be used in aqueous solution instead of glycerol to soften water-soluble plastics. The ethers have been suggested as softeners for casein, nitrocellulose or rubber.<sup>102</sup> When these hydroxyethyl ethers are treated with polybasic acids, heavy, balsam-like liquids are produced.

Pentaerythritol can also be treated with ethylene oxide in the presence of boric acid. The product is a viscous liquid insoluble in water, acetone and alcohol but soluble in many organic solvents.<sup>103</sup> The reaction of other alkylene oxides (propylene oxide, tetrahydrobenzene oxide) with pentaerythritol results in the production of etherified alcohols of high boiling point and of a viscous nature which find use in paper making, in explosives, in textile processes, as lubricants and as solvents or separating agents. These esterified alcohols when acetylated with either monobasic acids or polybasic acids give plasticizing substances and camphor substitutes. The nitric acid esters may be used in films, plastics, lacquers and explosives.<sup>104</sup>

Ethylene oxide may also be used to neutralize the acidity of resins. For example, a hard, fusible resin of acid number 130, obtained by heating 444 parts phthalic anhydride and 184 parts glycerol, was treated in an autoclave with about 140 parts ethylene oxide for six hours at 150°C. The product was a light-colored, clear, viscous balsam whose acid number was zero.<sup>105</sup>

Ethylene oxide reacts with cellulose to form hydroxyethyl ethers which, when treated with polybasic acids, form esters having a resinous character. They may be molded or used in lacquers.<sup>166</sup>

Ether-alcohols, other than the hydroxyalkyl ethers, also yield resins. Lawson<sup>167</sup> heated monoethylin (glycerol monoethyl ether) with phthalic anhydride and obtained a product which can be used with nitrocellulose or ethyl cellulose in lacquers. Hahn<sup>168</sup> formulated a cellulose acetate lacquer consisting of 12 parts of monoethylin phthalate resin, 12 parts cellulose acetate and 6 parts of a softener (diethyl or dibutyl phthalate) dissolved in 79 parts by weight of solvent. Another resin from monoethylin is made by heating 1 mol of glycerol ether with 2 mols of benzoylbenzoic acid at 175-250°C. for 3-14 hours.<sup>169</sup> Nitrocellulose plasticizers can be prepared from the acid phthalic ester of monoethylin by esterifying the free carboxyl groups with a monohydric alcohol. Butyl monoethylin phthalate is a substance of this type.<sup>170</sup>

Scheiber<sup>171</sup> also used polyhydric alcohols which had been partly etherified by a monohydric alcohol. These are condensed with polybasic acids by heating at about 200°C. For example, he made a resin by heating phthalic anhydride and glycerol monomethyl ether.

Hoover<sup>172</sup> used glycerol ethers such as the monophenyl or monotetrahydrofurfuryl derivatives. A mixture of 420 parts of  $\alpha$ -glyceryl phenyl ether (1-phenoxy-2,3-propanediol,  $\text{CH}_2\text{OHCHOHCH}_2\text{OC}_6\text{H}_5$ ) and 370 parts of phthalic anhydride are brought to 220-225°C. during the course of 2 to 3 hours and heating is continued within this range of temperature until a test sample has an acid number of 10 or less. The finished product is a hard clear resin having a brownish-red color. It is soluble in organic esters and aromatic hydrocarbons and in the mixtures of esters, alcohols and hydrocarbons ordinarily used in lacquer compositions. It is compatible with nitrocellulose in all proportions. Another resin is made by heating 112 parts of the tetrahydrofurfuryl ether of glycerol ( $\text{C}_6\text{H}_5\text{OCH}_2\text{CHOHCH}_2\text{OH}$ ) and 96 parts of phthalic anhydride. The finished resin has an acid number of approximately 10 and is a soft, clear mass, dark brown in color. It is soluble in acetone, or in a mixture of alcohol and benzene. The resin from phenol glycerol ether and phthalic anhydride can be incorporated with rubber and the mixture vulcanized to yield a rubber mass of increased resistance to chemical and electrical effects.<sup>173</sup>

#### PENTAERYTHRITOL

By the condensation of formaldehyde and acetaldehyde in the presence of calcium hydroxide, pentaerythritol, a tetrahydric alcohol, is obtained.<sup>174</sup>

on heating with dicarboxyethers or with thio-ethers and their anhydrides (diglycolic acid, carboxymethyl ether of salicylic acid, methyl diglycolic acid and thio-diglycolic acid, sulphidodiacetic acid), yield resins which form substitutes for glass, horn or shellac.<sup>188</sup>

#### MIXTURES OF POLYHYDRIC ALCOHOLS

Hill and Walker<sup>184</sup> used a mixture of ethylene glycol and glycerol to make resins of improved solubility and low acid number. Ordinary phthalic glyceride resins are very sparingly soluble in ester solvents, have a high acid number and if heated too long they change to an infusible, insoluble form. In order to make a more soluble resin, the glycerol is partly replaced by glycol. The incorporation of a dihydric alcohol allows heating to a high temperature without causing insolubility. A transparent, brittle resin made from 370 parts phthalic anhydride, 250 parts glycerol and 50 parts ethylene glycol, after heating 5 hours at about 200°C. was still soluble and had an acid number of only 2.7. These resins may be made in one step, or phthalic glycol resin and phthalic glyceride may be fused together. Kienle<sup>185</sup> also described polybasic acid resins from glycerol and glycol, diethylene glycol or propylene glycol.

#### MONOHYDRIC ALCOHOLS

Part of the polyhydric alcohol used in the resin reaction with polybasic acids may be replaced by monohydric alcohols (ethyl, amyl, butyl, allyl, diacetone alcohols or borneol). The products thus obtained are soft, depending upon the amount of monohydric alcohol employed and are useful for coating wires and sheet metal because of their high flexibility and water-resistivity. A clear and transparent resin can be made up as follows: To the reaction product of 285 parts of phthalic anhydride and 40 parts of butyl alcohol, which have been heated for 1.5 hours at 160°C., 100 parts of glycerol are added and the mass re-heated to 200-220°C.<sup>186</sup> Hill and Walker<sup>187</sup> made a phthalic anhydride-glycerol-butyl alcohol resin as follows: To a mixture of 18.5 parts of butyl alcohol and 74 parts of phthalic anhydride heated under an air condenser to about 200°C. for an hour, 23 parts of glycerol are added and the temperature held at 185-195°C. for 4 hours. On cooling, the product is a tough resin soluble in acetone and having an acid number of 48. If the butyl alcohol is replaced by glycerol, the resin gels in about 3 hours and the acid number just before gelation is close to 100. Cyclohexanol may be used in the same way as butanol.

Arsem<sup>188</sup> sought to prepare ester groupings containing no free carboxyl groups or hydroxyl groups. The product of butyl alcohol, phthalic anhydride and glycerol would be represented as follows:

<sup>188</sup> W. C. Arsem, U. S. P. 1,935,791, Dec. 12, 1933; *Chem. Abs.*, 1934, 28, 1533. See also German P. 609,249, 1936, to Dageb A.-G.; *Chem. Abs.*, 1936, 29, 3072.

By first heating two mols (296 grams) of phthalic anhydride and one mol (92 grams) of glycerol at 150-200°C., glyceryl phthalic acid is produced:

To the latter is added a large excess of butyl alcohol, benzene and 10-20 g. of sulphuric acid. The butyl alcohol is distilled off, water being removed from the reaction as a constant-boiling mixture with benzene to yield the compound:

More alcohol and benzene are added and distillation carried out at reduced pressure to remove traces of water. By initially using 3 mols of phthalic anhydride to one mol of glycerol and esterifying similarly with butanol, the hydroxyl-free ester is obtained. Swallen and Ireys<sup>190</sup> have improved the method of Arsem by using a petroleum hydrocarbon to remove undesirable by-products. One mol (92 g.) of glycerol and 1.5 mols (222 g.) of phthalic anhydride are fused at 130-135°C. and the mass is then heated at 160°C. for 10 minutes. To this product are added 300 g. of n-butyl alcohol together with 22 g. of hydrochloric acid (sp. gr. 1.2). The resulting mixture is heated quickly to 110° C. and distilled first through a fractionating column and then *in vacuo*. The material is subsequently heated at 175-190°C. for 10-30 hours and then agitated with a petroleum hydrocarbon (b.p. 95-160°C.) at 90°C. for a few hours. The extraction with the hydrocarbon is continued until the resin is free of dibutyl phthalate. The residual hydrocarbon is removed along with by-products by heating to 120°C. under reduced pressure.<sup>190</sup>

Cetyl alcohol ( $\text{C}_{18}\text{H}_{37}\text{OH}$ ), on reacting with phthalic anhydride, yields a waxy ester; cetyl alcohol, phthalic anhydride and glycerol, a viscous balsam-like resin. These cetyl alcohol esters may be blended with nitrocellulose to produce films of a clear transparent character.<sup>191</sup> The resin made from 121 parts of cetyl alcohol, 148 parts of phthalic anhydride and 47 parts of glycerol by heating to 250°C. for 15 minutes and subsequently at 270°C. for 25 minutes is a viscous balsam, melting at 12°C. and of acid number 40. The products are miscible with butyl acetate, toluene and naphtha but not with denatured alcohol. Brubaker<sup>191a</sup> used a mixture of phthalic anhydride, glycerol and lauryl alcohol or the alcohols obtained by catalytic hydrogenation of fatty oils.

Terpene derivatives can also be included in the resin. Adams<sup>192</sup> heated a mixture of phthalic anhydride and terpene hydrate at 200°C. until a clear liquid was obtained. Glycerol was then added and the heating continued until a sample of the resin hardened on cooling. Borneol, camphoric anhydride and gutta-percha can be used. The resins obtained in this way have good water-resistance.

## MISCELLANEOUS ALCOHOLS

Alcoholamines (mono-, di- or triethanolamine) form resins when heated with phthalic anhydride. The products are used as softening agents or as accelerators for vulcanization.<sup>196</sup> Weisberg and Greenwald<sup>194</sup> extended this reaction to include a combination of triethanolamine, phthalic anhydride and oleic acid. The amine and acid are first allowed to react at 150°C. whereupon the oleic acid is added. Substitution of citric acid in place of the oleic leads to considerable foaming.<sup>195</sup>

Burns<sup>199</sup> has used hexahydroxycyclohexane or its mono- or dimethyl ether (quebrachitol) as a polyhydric alcohol with phthalic anhydride in the preparation of resins. Other alcohols include dimethyloldimethylmethane, trimethylolethylmethane, 2,2,6,6-tetramethylolcyclohexanol and  $\beta$ -2-quinolylpropane- $\alpha,\gamma$ -diol.<sup>197</sup>

Cellulose itself reacts with phthalic anhydride in the presence of pyridine at 60°C. to form a white mass.<sup>198</sup> Cellulose phthalate can also be prepared by treating undissolved cellulose (either modified or partially etherified or esterified) with phthalic anhydride along with a tertiary organic base until a dope is formed. Under these conditions one of the carboxyl groups of the phthalic anhydride is esterified with the cellulose whereas the other combines with the organic base. Treatment with acid removes the base. When the reaction is carried out below 95°C. in the presence of benzene or ethylene dichloride and the compound precipitated, a product is formed which is soluble in water, rendered basic with pyridine, or in pyridine solutions of benzene or of tetrachloroethane.<sup>199</sup>

Cellulose can be similarly treated with succinic, glutaric, diglycolic, dilactic, dihydracrylic, thiodiglycolic, thiolactic acids and the like.<sup>200</sup> These acids may be neutralized with ammonia, alkylolamines or treated with heavy-metal salts.<sup>201</sup> Cellulose triethanolamine phthalate is used in making anti-halation coatings for backing photographic films.<sup>202</sup>

## Chapter 43

### Modified Alkyd Resins

#### I. Use of Non-Drying Oils and Acids Effect of Natural Resins

The modification of alkyd resins with monobasic acids imparts increased solubility to the resin. Lower aliphatic acids (acetic, butyric) have a pronounced softening action. Acids from non-drying oils (stearic, palmitic, oleic, ricinoleic) lead to the formation of products of greater flexibility.<sup>1</sup> As a rule the free acids are used instead of the oils themselves since, with the exception of castor oil, it is difficult to incorporate the glyceride oils in an alkyd resin unless indirect methods are used. Other monobasic acids used with alkyd resins include natural resins (rosin, copal) which increase solubility and brittleness. The main use for all these modified resins is in coating compositions, particularly nitrocellulose lacquers.<sup>2</sup>

#### USE OF ACIDS FROM NON-DRYING OILS

Arsem<sup>3</sup> described the preparation of glycerol phthalate resins modified by oleic acid. Such a product is obtained when 92 parts of glycerol are heated with 148 parts of phthalic anhydride at 200-210°C. until evolution of water vapor ceases, after which a mixture of 141 parts of oleic acid and 37 parts of phthalic anhydride is added. On further heating at 215-230°C. for 1.5 hours a deep red liquid is obtained which congeals at room temperature. It is soluble in organic hydrocarbon-solvents, and may be hardened by prolonged heating (20-30 hours) at 160°C., but retains its flexibility. Increase in the proportion of oleic acid improves the elasticity. The hardened resin, which is transparent in thin layers, is insoluble, unattacked by weak acids or by chlorine, and little affected by long heating at 150°C. The liquid resin or its solutions, or solutions of a product partially hardened at 160°C., may be used for impregnating fabrics, wood or paper, or as a direct insulating coating for metal surfaces.

One application of the resin made by reaction of glycerol with phthalic anhydride and oleic acid is to coat electrodes which come in contact with litharge. The latter has been found to affect linseed oil but does not destroy the alkyd coating. The resin is applied in acetone solution and when the coating is baked a surface is obtained which exhibits a greater degree of resistance to water than is shown by shellac.

The addition of sulphur<sup>4</sup> to the oleic acid-modified alkyd yields rubber-like masses insoluble in solvents, although somewhat attacked by benzene and by xylene. These are infusible, but char like rubber on heating. By use of molecular

<sup>1</sup> The monobasic acids from drying oils also impart increased solubility and flexibility and at the same time cause the resin to be more susceptible to heat-hardening. (See Chapter 44.) In contrast, the non-oxidizable acids of non-drying oils make the resin less sensitive to heat-hardening, the effect depending upon the proportion of monobasic acid used.

<sup>2</sup> See Chapter 47.

<sup>3</sup> W. C. Arsem, U. S. P. 1,098,777, June 2, 1916, to General Electric Co.; *Chem. Abs.*, 1914, 8, 2818.

<sup>4</sup> W. C. Arsem, U. S. P. 1,083,106, Dec. 22, 1913, to General Elec. Co.; *Chem. Abs.*, 1914, 8, 830.

proportions of glycerol and phthalic acid, with subsequent addition of 1 mol of oleic acid at 210-215°C., a viscous liquid is obtained to which 10-20 per cent of sulphur is added. Up to 19 per cent of castor oil may also be incorporated. The product may be used for stoppers, washers and molded material in place of rubber.

By the use of lactic acid or chloroacetic acid with glycerol-phthalic anhydride, resins of low flow-point are obtained; thus the resin produced by one-quarter mol of chloroacetic acid and one and three-eighth mols of phthalic anhydride per mol of glycerol has a flow point of 88°C., is hard and brittle and is rendered infusible by heating at 160°C. for 8 hours.<sup>5</sup> Butyric acid<sup>6</sup> combined with glycerol phthalate yields a very soft rubber-like product, which may be dissolved in acetone and used to impregnate wood, cloth and paper, the resin being rendered insoluble and infusible by heating 2 or 3 hours at 100-120°C. while still retaining flexibility. Such a resin may be procured by heating 22 parts of glycerol phthalate (from 2 parts by weight of phthalic anhydride and 1 part of glycerol) with 10 parts of butyric or isobutyric acid in glycerol for 8-24 hours. The temperature is finally raised to 300°C.

Arsem<sup>7</sup> heated glycerol phthalate with stearic acid and obtained a soft, paraffin-like substance which was soluble in heavy hydrocarbons and had good insulative properties. Alkyd resins modified with stearic or other fatty acids are not homogeneous and contain ingredients which confer solvent retentiveness on their solutions. Quick-drying resins may be formed, however, by treating the mass with solvents<sup>8</sup> (gasoline or 95 per cent alcohol) which dissolve out the slow-drying constituents. The residual resins are then quicker-drying, and harden more rapidly under heat treatment. Addition of the acids derived from coconut oil to the stearic acid-modified alkyd also improves the drying qualities without impairing the fastness to light.<sup>9</sup> For example, a resin was prepared from 100 parts of glycerol, 160 parts of phthalic anhydride, 45 parts of stearic acid and 45 parts of the distilled acids of coconut oil by heating at 200-290°C. in an inert atmosphere.

Cottonseed oil acid-modified glycerol phthalate resins are soluble in acetone and may be incorporated with nitrocellulose in any proportion to form lacquer coatings.<sup>10</sup> Soluble resins for coating compositions are also made by treating a glycerol phthalate-cottonseed oil acid resin with 1-2 per cent of its weight of sulphur monochloride.<sup>11</sup> The product from 80 parts of phthalic anhydride, 50 parts of glycerol and 45 parts of the distilled fatty acids from cottonseed oil, brought to acid number 25 by heating to 230°C., is dissolved in toluene-monochlorobenzene, or benzene-ethyl acetate mixture, and treated with 1 per cent of sulphur monochloride. The free acids are neutralized after 2 hours with magnesium oxide giving a solution which may be incorporated with cellulose esters, plasticizers and pigments. By heating together glycerol, phthalic anhydride, oleic acid and ammonium acid sulphate to 170-240°C., a vigorous reaction sets in and a dark resin is produced which is soft, transparent and adhesive. The composition is soluble in benzene and toluene and blends well with nitrocellulose in a solvent consisting of butyl acetate and toluene.<sup>12</sup>

Modified alkyd resins, such as that derived from 80 parts of phthalic anhydride,

<sup>10</sup> Carleton Ellis, U. S. P. 1,923,714, Aug. 22, 1932, to Ellis-Foster Co.; *Chem. Abs.*, 1933, 27, 5560.

<sup>11</sup> Carleton Ellis, U. S. P. 1,811,115, June 23, 1931; *Chem. Abs.*, 1931, 25, 8049.

<sup>12</sup> Carleton Ellis, U. S. P. 1,970,518, Aug. 14, 1934, to Ellis-Foster Co.; *Chem. Abs.*, 1934, 28, 6330.

50 parts of glycerol and 45 parts of cottonseed oil acids<sup>12</sup> thinned with a hydrocarbon solvent, have been used with wood flour and pigments, for a wood filler or coating composition which bonds well with superposed lacquer.

In the manufacture of water-resistant abrasants (emery and whetstone), a binding composition is made up with a resin resulting from condensation of glycerol, glycol and a fatty acid of at least ten carbons (lauric, palmitic, and stearic) and a polybasic acid (phthalic, maleic or succinic).<sup>14</sup>

When the oleic acid-modified glycol-phthalate resin is sulphonated with chloro-sulphonic acid, water-soluble resinous products result which act as resolving agents for water-in-oil emulsions.<sup>15</sup>

By employing a succinic acid-benzoic acid-glycerol mixture<sup>16</sup> light-colored resins of great toughness are formed which blend well with cellulose esters. Such a product is obtained from 61 parts of benzoic acid, 59 parts of succinic acid and 46.5 parts of glycerol, heated slowly to 290°C. and chilled rapidly. The resin may be used with, for example, an equal weight of cellulose acetate in a mutual solvent, such as a mixture of 10 per cent acetone, 30 per cent ethyl oxybutyrate and 60 per cent ethylene dichloride. The product from succinic acid and dihydroxy-diethyl ether (diethylene glycol) has especially high blending powers with nitrocellulose.

The ester prepared from benzoic acid and glycerol,<sup>17</sup> though soluble in ethyl, butyl and amyl acetates, is nevertheless quite soft. Addition of phthalic anhydride improves the hardness and at the same time does not limit the solubility in ester solvents provided that not too much phthalic anhydride is used. Glycerol benzoate-phthalate is of a pale color when prepared by heating in a vacuum and is soluble in ester solvents, softens easily and mixes well with nitrocellulose to form a lacquer. Ethylene glycol, propylene glycol and chlorohydrins may replace the glycerol with no appreciable change in properties.

#### USE OF FATTY OILS

Howell<sup>18</sup> found that both the toughness and the flexibility of alkyd resins were improved by the incorporation of castor oil. He first partially esterified 184 parts of glycerol with 296 parts of phthalic anhydride by heating for about 1 hour at 180°C.; 320 parts of castor oil were then added. At first the oil formed a distinct layer but on continued heating at 220°C. solution took place and a homogeneous liquid resulted. At this stage the resin was soluble in alcoholic benzene (1-3) but quite insoluble in benzene itself. By further heating to 280°C. a violent gas evolution occurred and a vesiculated infusible product was obtained.

This resin may be further modified by the addition of oleic acid<sup>19</sup> in accordance with the following procedure: 92 parts of glycerol and 148 parts of phthalic anhydride are heated to 200°C. and 70.5 parts of oleic acid, 70.5 parts of castor oil and 37 parts of phthalic anhydride added. The flexible condensation product is soluble in hydrocarbons (benzene, naphtha, turpentine, coal-tar oil) and forms a varnish for impregnating paper. When mixed with a mineral filler the resin may be applied directly to metallic surfaces. The hardened resin is resistant to dilute acid or alkali but is attacked by more concentrated solutions.

<sup>17</sup> T. F. Bradley, U. S. P. 1,956,559, May 1, 1934, to Ellis-Foster Co.; *Chem. Abs.*, 1934, 28, 4255.

<sup>18</sup> K. B. Howell, U. S. P. 1,098,728, June 2, 1914, to General Elec. Co.

<sup>19</sup> E. S. Dawson, U. S. P. 1,141,944, June 3, 1915, to General Elec. Co.; *Chem. Abs.*, 1915, 9, 1973.

The castor oil-modified alkyds are compatible with nitrocellulose<sup>20</sup> and in admixture with the latter form lacquers for coating artificial leather.<sup>21</sup> Castor oil resins can be bleached by heating them with a small amount of phosphoric or boric acid and exposing to light for several days.<sup>22</sup>

Elastic products, approximating the properties of natural Hevea rubber are made, according to Bruson,<sup>23</sup> by heating castor oil with an aliphatic dibasic acid (adipic, pimelic, suberic, azelaic, or sebacic) and a polyhydric alcohol. Drying oils (linseed oil) may also be incorporated. In this way, by heating 55 parts of glycerol, 181.8 parts of sebacic acid and 189.6 parts of castor oil for 10 hours at 190–200°C., a rubbery mass is produced, soluble in butyl alcohol and toluene. Longer heating insolubilizes it, but the material is capable of being rendered soluble again by mastication in a rubber mill. The products may be used as plasticizers for cellulose nitrate lacquers and as bonding materials for rubber, wood flour and clay pigments. In place of castor oil, its hydrolytic product, ricinoleic acid, may be substituted.<sup>24</sup>

Resins can also be prepared from oxidized fats. When air or other gas containing oxygen is forced through the glycerol esters of fatty acids (glycerol-oleic ester), a liquid of high viscosity is obtained, provided the oxidation has not been allowed to proceed to the gelatinizing stage. Condensation with maleic anhydride then yields a resin with an acid number of 30–40.<sup>24</sup>

An interesting development arises from the observation that geometrical isomerism has a distinct bearing on the characteristics of the resin. The  $\beta$ -form of the acid yields products which are harder and have greater resistance to aging and oxidation than those from the  $\alpha$ -acid.<sup>25</sup> The  $\alpha$ - and  $\beta$ -forms are related as "cis" and "trans" isomers, the low-melting  $\alpha$ -form being converted to the higher-melting  $\beta$ -form by nitrous acid:

Natural fats (olive oil and castor oil) of iodine number more than 70 are converted by shaking with freshly prepared nitrous acid solution to give the  $\beta$ -form, and the resulting eläidin, or ricineläidin, is reacted with glycerol and phthalic anhydride. The  $\beta$ -form of olive oil (37.7 parts) and glycerol (18.5 parts) are heated with stirring in the presence of 0.05 part of sodium hydroxide for an hour at 250°C. Phthalic anhydride (43.8 parts) is then added in small portions and heating continued for about 5 hours at 200°C. until a resin of acid number of 55–60 results. The product is soluble in ethyl alcohol, toluene and butyl acetate and alcohol-hydrocarbon mixtures. A clear, pale resin can be prepared from ricineläidin, adipic acid and ethylene glycol. These resins, which are soluble in hydrocarbons, acetone and esters, can be used as softeners in nitrocellulose lacquers.

## TREATMENT OF CASTOR OIL WITH DIBASIC ACIDS

Castor oil,<sup>28</sup> which is essentially the glycerol ester of ricinoleic acid,

contains free hydroxyl groups and may be esterified with acids.<sup>27</sup> Oda<sup>28</sup> studied the reaction of phthalic anhydride and castor oil by heating the reactants at 190-245°C. in carbon dioxide and found that multimolecular compounds are formed. Citric and malonic acids react easily with castor oil whereas succinic and tartaric enter with difficulty. Castor oil with oxalic acid at 140-150°C. and 15 mm. pressure yields an acid ester as well as a condensation product of 2 mols of the oil to 1 mol of the acid.<sup>29</sup>

By heating 311 grams of castor oil and 100 grams of maleic acid for 18 hours at 110-120°C., a yellow, transparent gummy mass was obtained which was practically neutral and which was soluble in castor oil and in other oils under heat. In hot turpentine, a true solution is not formed but rather a viscous pseudo-solution.<sup>30</sup> Plastic materials are also obtained by reacting castor oil with the half-ester of maleic anhydride obtained by condensing equimolecular proportions of maleic anhydride with a monohydric alcohol (cyclohexanol, hexyl, capryl, benzyl alcohols, borneol,  $\alpha$ -terpineol, diethylene glycol monobutyl ether or octadecanol). The syrupy products prepared under these conditions are soluble in benzene, toluene, acetone, butyl acetate, petroleum naphtha and are compatible with nitrocellulose.<sup>31</sup>

Castor oil either free or hydrogenated can be condensed with phthalic anhydride by heating at 140°C. for 1 hour in such a manner that the acid ester is formed. On neutralization, metallic salts are obtained which are soluble in butyl alcohol, butyl or ethyl acetate and which are compatible with nitrocellulose. When incorporated into films, there is an improved fastness to light.<sup>32</sup> By carrying out the reaction at 220°C. with phthalic or maleic anhydride and castor oil, the compound may be used directly as a softening agent for nitrocellulose<sup>33</sup> or for the formation of nitrocellulose films.<sup>34</sup> Reaction can also be effected at 100°C. provided a condensing agent (zinc chloride) is used. The product is a pale yellow-brown oil.<sup>35</sup> Heating castor oil with phthalic anhydride to 150-180°C. yields a stiff oil which can also be mixed with cellulose esters.<sup>36</sup> Moore<sup>36a</sup> made a resinous product

<sup>28</sup> For the use of castor oil as a raw material for plasticizers and resins, see L. Light, *Chem. Age*, 1934, 30, 491; *Chem. Abs.*, 1934, 28, 4921. Treatment of castor oil with 0.5 per cent of an alkali metal oxalate or oxalic acid or its esters retards rancidification of the oil when used as a softener in nitrocellulose coating compositions. See T. H. Rogers, U. S. P. 1,826,258, Oct. 6, 1931, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1932, 26, 613.

<sup>27</sup> For the inner-esterification of castor oil and derivatives, that is, the formation of estolides, see Chapter 61.

<sup>36a</sup> C. G. Moore, Canadian P. 348,040, 1935, to Glidden Co.; *Chem. Abs.*, 1935, 29, 3422.

for use in nitrocellulose lacquers by heating 186 parts castor oil and 30 parts succinic acid to 180°C., at which point condensation actively begins. The temperature was finally raised to 260-310°C. until the resin had an acid number of about 20.

Castor oil has also been esterified with the natural acidic resins. By heating rosin with castor oil or with ricinoleic acid *in vacuo* or in an inert atmosphere at 260°C., an acid-free viscous oil is obtained which acts as a softening agent for celluloid, casein or phenol-formaldehyde resins.<sup>37</sup> The castor oil fatty acids may first be dehydrated before esterification with natural resins. In this instance, however, glycerol should be added. Scheiber<sup>38</sup> in subjecting ricinoleic acid or the mixture of castor oil fatty acids to prolonged heating *in vacuo*, prepared an isomeric linoleic acid. This acid was first esterified with an excess of glycerol and the excess esterified with a resin acid (copal, rosin). On adding a diluent a varnish is obtained, the drying capacity of which may be regulated by the addition of driers. The same method can be used with a mixture of acids, for example those derived from semi- or non-drying oils together with ricinoleic acid.<sup>39</sup>

The resin of acid number 50 derived from glycerol (18 parts), phthalic anhydride (44 parts) and castor oil (38 parts) at 200°C. can be modified with polymerized terpene resins in the following proportions: 75 per cent of alkyd resin, 21.2 per cent of "polymerized terpene resin G"<sup>40</sup> and 3.8 per cent "polymerized terpene resin E."<sup>41</sup> An adhesive for laminated material is thus formed.<sup>42</sup>

Water-soluble products, used as wetting-agents in dyeing, are obtained by treating higher unsaturated fatty acids with a sulphonating agent in the presence of sulphonated aromatic carboxylic acids. Thus, castor oil or ricinoleic acid is treated with a mixture of phthalic acid anhydride- $\beta$ -sulphonic acid and sulphuric acid,<sup>43</sup> or with phthalic acid anhydride- $\beta$ -sulphonic acid *in vacuo* at 150-160°C.<sup>44</sup> The product of the latter process is used as a wetting and finishing agent for textiles. Wetting, penetrating, foaming and dispersing agents are also formed when aliphatic acids with more than 8 carbon atoms (ricinoleic and hydroxy-stearic acids) or aromatic acids ( $\beta$ -naphthoic acid) are sulphonated and esterified with glycol monomethyl or monoethyl ether.<sup>45</sup> The castor oil-modified glycerol phthalate of low acid number has also been employed in dressing textiles.<sup>46</sup>

#### RESINS FROM POLYHYDROXY ACIDS

Bruson<sup>47</sup> has utilized polyhydroxy acids for the preparation of alkyd-type resins. Acids available for the purpose include dihydroxystearic acid,  $C_{17}H_{33}(OH)_2COOH$ , trihydroxystearic acid,  $C_{17}H_{33}(OH)_3COOH$ , tetrahydroxystearic acid,  $C_{17}H_{33}(OH)_4COOH$ , hexahydroxystearic acid,  $C_{17}H_{33}(OH)_6COOH$ , and dihydroxybehenic acid,  $C_{21}H_{41}(OH)_2COOH$ , which may be obtained by regulated oxidation of the unsaturated oils by means of alkaline potassium permanganate.

These acids, containing two or more hydroxyl groups, may be condensed with polybasic acids, such as phthalic, succinic, maleic, adipic, diphenic, naphthalic acids

<sup>46</sup> German P. 605,573, 1934, to Firma Louis Blumer; *Chem. Abs.*, 1935, 29, 1999.

<sup>47</sup> H. A. Bruson, U. S. P. 1,815,886, July 21, 1931, to Röhm & Haas Co.; *Chem. Abs.*, 1931, 25, 5525. German P. 593,539, 1934, to Chem. Fabr. K. Albert, G.m.b.H.; *Chem. Abs.*, 1934, 28, 6004. See also German P. 611,056, 1935, to Chem. Fabr. K. Albert, G.m.b.H.; *Chem. Abs.*, 1935, 29, 4103.

and the like to form resins, which in turn may be modified by incorporating a proportion of fatty oils. As an example 9,10-dihydroxystearic acid (obtained by permanganate oxidation of oleic acid) is mixed with an equimolecular quantity of phthalic anhydride, and heated to 190°C. As condensation proceeds, the mixture yields a hard translucent wax, which eventually forms an oily liquid, becoming more viscous as heating is continued. On cooling, a rubbery mass is obtained which is soluble in acetone, but becomes insoluble on long heating. Incorporation of drying oils leads to viscous oily masses useful for coating compositions. In general, the products are suited for coating textiles, leather, rubber and thin sheet metal, where flexibility and waterproofness are prime requisites.

If, on the other hand, the polyhydroxy acids are esterified with alcohols, products can be prepared which serve as plasticizers for cellulose derivatives.<sup>48</sup> Glycols give rise to viscous oils, whereas glycerol or mannitol first yields a clear liquid, then a soluble rubbery material and finally an insoluble plastic mass.

A liquid acid portion of the oxidation of paraffin hydrocarbons,<sup>49</sup> which consists essentially of hydroxycarboxylic acids and which is insoluble in light petroleum, can be esterified with a polyhydroxy alcohol (glycol, glycerol) to yield a rubbery plastic composition. Before or during the heating process, siccatives (lead oxide, linoleic acid or linolein) may be introduced,<sup>50</sup> or air may be passed through.<sup>51</sup> Sulphur or sulphur monochloride can be added also. A similar class of substances results from the unsaturated acids of oxidized paraffin wax.<sup>52</sup> The carboxylic acids from the oxidation of paraffin hydrocarbons can be condensed with glycerol and phthalic anhydride to yield a resin.<sup>53</sup>

By heating a polyhydric alcohol with bleached montan wax, together with a monobasic fatty acid (coconut oil fatty acids,<sup>54</sup> ricinoleic acid),<sup>55</sup> an aromatic (salicylic) or a hydroaromatic acid,<sup>56</sup> and with or without an accelerator (sodium bisulphate, boric acid, or anhydrous zinc chloride), products are obtained which resemble natural waxes. Any free acid is converted into an ester, an amide or a salt. Fillers, dyes, gums, plasticizers and other resinous compounds may be added and the final material is pressed and heated after comminution.<sup>57</sup> Montan wax can also be treated with glycerol in the presence of sodium hydroxide or lead oxide. The resulting composition can then be esterified with phthalic anhydride, rosin, and drying oil acids.<sup>58</sup>

#### EFFECT OF NATURAL RESINS

By the incorporation of certain other constituents both the properties and the applications of alkyd resin products are altered considerably. When the added ingredient is a natural resin the alkyd resins so modified are well known under the name "Teglac,"<sup>59</sup> (see Fig. 127) and some products of the Teglac type approxi-

<sup>59</sup> Teglaacs are products of the American Cyanamid Co.

mate in their physical properties those of the natural resins. For the most part, however, they lack the toughness of alkyd resins made with oil modifying agents and generally are not recommended for use alone in coating compositions. They are, nevertheless, more truly compatible with nitrocellulose than the greater part of the natural resins. Hence the Teglac materials have a wide use in lacquer preparations. They have also been cooked into varnish, and incorporated into enamel and paint products.<sup>60</sup>

Natural-resin-modified alkyds are easily soluble in cold toluene, in turpentine, in Cellosolve and in similar solvents, and are suited for the production of glossy brushing lacquers. Their exceptionally high index of refraction imparts a gloss and a depth of film similar to that secured with oleo-resinous varnishes. Blending of a proportion of the natural-resin-alkyd with a drying oil-alkyd lacquer results

FIG. 127.

Fragment of Teglac Which Shows a Peculiar Conchoidal Fracture.

in improved hardness to the latter; for this reason the former are especially well adapted to the production of sanding sealers.<sup>61</sup>

Metallic driers cannot, as a rule, be incorporated with rosin-phthalic glyceride varnishes by the common process of adding the accelerator to the bodied oil and resin at about 200°C. Precipitation occurs either at once or upon aging, regardless of whether linseed or tung oil is used; the drier is removed from solution by the acid constituents present in the resin. The driers may, however, be added to the cold varnish, in the form of their solutions in oil, without any precipitation ensuing. This tendency to precipitate the added metallic driers may be partially overcome by removing free phthalic anhydride from the resin.

Resins, which are soluble in acetone, in acetone-alcohol or in acetone-benzene mixtures and which blend with nitrocellulose to yield good films, are formed by incorporating rosin in a glycerol phthalate resin. A resin of this type is formed<sup>62</sup> when 50 parts of phthalic anhydride, 33 parts of glycerol and 75 parts of light-colored rosin are heated to 250°C. To the clear product thus formed (acid number 68), 10 parts of glycerol are added, and further heated to 290°. A clear transparent resin is produced, somewhat darker than the original rosin,

<sup>60</sup> M. R. Trimmer and J. M. Sanderson, *Paint, Oil, Chem. Rev.*, 1931, 91 (23), 19; *Chem. Abs.*, 1931, 25, 3334.

<sup>61</sup> For the use of Lewisol No. 18 resin as a quick-drying sanding sealer see *Paint, Oil, Chem. Rev.*, June 14, 1934, 33.

<sup>62</sup> Carlston Ellis, U. S. P. 1,732,566, July 30, 1929; *Chem. Abs.*, 1929, 23, 4533.

and having an acid number of 12.7. The use of 100 parts of rosin, 15 parts of phthalic anhydride and 25 parts of glycerol heated to 290°, yields a hard resin of acid number 7.7.

In the preparation of such resins, lime, zinc oxide or baryta may be added. The basic substances produce a hardening effect, inasmuch as they combine with any free acid. (See Chapter 37.) If the resin, after the addition of the bases, be heated until combination with free acid is complete, the acid number of the final product may be reduced to a low value. A mixture of equal parts of shellac, glycerol and phthalic acid heated to 295°C. yields a dark resin which softens at about 60°C. to a rubbery mass, and ultimately fuses between 120° and 150°C.

An important property of the rosin-phthalic glyceride resins is that already mentioned, that is, their compatibility in all proportions with nitrocellulose.<sup>62</sup> Addition of as little as 5 per cent of nitrocellulose or celluloid (conveniently in the form of scrap motion-picture film) greatly improves the toughness of the resins. By using a higher proportion of nitrocellulose the toughness is still further enhanced, so that a resin containing 25-30 per cent of nitrocellulose in a solvent may be poured out onto glass and will dry to a clear coherent film which may be removed in its entirety. Such hardened resins may be used as varnishes or japans, as substitutes for hard rubber and for tough transparent sheets, although the color of the natural-resin-modified alkyd is not as light as that of good quality nitrocellulose. The presence of a considerable or preponderant proportion of rosin-phthalic glyceride apparently reduces the inflammability of the nitrocellulose, and the latter in turn increases the water-resistance of the resin. An example of a coating for floors is that produced by dissolving 25 parts of rosin-phthalic glyceride resin and 50 parts of scrap motion-picture film in a mixture of 50 parts of benzene and 100 parts of acetone. The viscous solution dries to a tough, transparent, light-yellow film. Congo copal can be used to replace the rosin in the rosin-glycerol phthalate resins; the copal-alkyds are also compatible with nitrocellulose.<sup>64</sup>

For blending with nitrocellulose, it is advantageous to employ products of an acid number less than 20 and devoid of free glycerol.<sup>65</sup> The latter being hygroscopic, tends to give rise to turbidity or to "blushing" of the film. The function of the natural resins, co-esterified with a polyhydric alcohol-polybasic acid resin, is to produce soluble, water-resistant resins of low acid number. Although natural resins<sup>66a</sup> of various kinds such as copal, manila or dammar, may be used in conjunction with the various possible combinations of alkyd resins, the low cost and wide range of useful properties has led to the greatest development of rosin-glycerol phthalate resins. A useful resin fulfilling the above conditions, that is, of low acid number and the absence of free glycerol, is made by heating 1340 parts of WW rosin, 308 parts of phthalic anhydride and 348 parts of glycerol, with agitation, to 290°, until the acid number of a test sample is below 20. The product is light-colored and soluble in benzene. It contains the equivalent of 3 parts of rosin glyceride to 1 part of phthalic glyceride reacted together in such a manner as to form a homogeneous resin complex. Such compositions may be given an increased flexibility and improved adhesion, when employed in conjunction with nitrocellulose, by incorporating a softening agent such as castor oil, diethyl phthalate or, less appropriately, triacetin. A coating composition may be derived from 3 parts of the above resin and 2 parts of low-viscosity nitrocellulose in the form of a 50 per cent solution.

The acid number may further be reduced by neutralization of the resin with

<sup>62</sup> H. M. Weber, U. S. P. 1,722,776, July 30, 1929, to Ellis-Foster Co.; *Chem. Abs.*, 1929, 23, 4582.

<sup>64</sup> H. M. Weber, U. S. P. 1,787,104, May 6, 1930, to Ellis-Foster Co.; *Chem. Abs.*, 1930, 24, 3595.

<sup>65</sup> Carleton Ellis, U. S. P. 1,843,869, Feb. 3, 1933, to Ellis-Foster Co.; *Chem. Abs.*, 1933, 26, 1812.

<sup>66a</sup> Carleton Ellis, U. S. P. 2,000,937, May 14, 1935, to Ellis-Foster Co.

aromatic amines.<sup>66</sup> Thus, 100 parts of a resin prepared as above (acid number 10.9) when heated at 290°C. with 5 parts of p-toluidine, yielded a product of acid number 4.9. By the use of 10 parts of the amine, the acid number was reduced to zero. The complete absence of free acid is advantageous in some molding compositions, and, in certain cases, in nitrocellulose lacquers. Phthalic glyceride resins of high acid number, which tend to become infusible on heating, may have their acid number considerably reduced, and at the same time their heat-convertibility subdued, by this method of amine neutralization. Fusible shellac substitutes may be made in this manner.

By a process of controlled atmospheric oxidation, the melting point of resins of this nature may be raised.<sup>67</sup> In the case of a rosin-phthalic glyceride which softened initially at 90°C., the softening point was raised to 99°C. by four days' heating at 50°, finally reaching 105°C. after a further two days' heating at 60°. The procedure is to heat the powdered resin in a shallow layer, at a temperature somewhat below the fritting point. With certain synthetic resins the oxidation may proceed to a point where insolubility occurs, although this is not the case with the rosin-phthalic glyceride. On the contrary, the resin becomes more soluble in lacquer solvents, and is rendered more valuable for the production of hard lacquer coatings. It is also feasible to incorporate catalysts (lead resinate) in the original resin to accelerate the oxidation process.

Resins of a lower melting point than an unmodified rosin-phthalic glyceride may be made by introducing a monobasic acid<sup>68</sup> such as benzoic. The property of compatibility with cellulose esters is thus retained, whereas the toughness and adhesion of the lacquer film are enhanced. The quantity of plasticizer may frequently be reduced when such resins are employed. Moreover, the employment of low-melting resins with nitrocellulose in plastic compositions decreases the danger of decomposing the cellulose ester. By appropriate choice of the organic acid, the softening point may, on the other hand, be raised, giving rise to harder films.

The incorporation into glycerol phthalate of fatty acids (stearic, dihydroxystearic) or aromatic monobasic acids (toluylbenzoic, benzoylbenzoic) and natural resins (rosin or Congo copal)<sup>69</sup> leads to the formation of light-colored products which are soluble in lacquer solvents and compatible with nitrocellulose. In these lacquers the nitrocellulose is not the chief constituent, but only a toughening and hardening agent. Substitution of pentaerythritol, or di- or triethylene glycol, for glycerol is advantageous in that it facilitates the formation of more homogeneous products. A resin illustrative of this type is produced by heating at 290°C. 45 parts of stearic acid, 45 parts of fused or "run" Congo resin, 74 parts of phthalic anhydride and 58 parts of pentaerythritol. The addition of small amounts of basic substances (urea) prevents the formation of insoluble substances from mixes which contain a large proportion of phthalic anhydride; the latter may be partly replaced by a monobasic acid. Resins from glycerol and polybasic acids, modified with copal, kauri, dammar or resin acids<sup>70</sup> or with cottonseed oil acids,<sup>71</sup> may be used with a lesser proportion of cellulose ester for coating compositions.

Bradley<sup>72</sup> sought to overcome the use of nitrocellulose entirely in lacquer compositions by using waxy substances in the alkyd resins. He first prepared a cottonseed acid-modified glycerol phthalate in the ratio of 90-100-160 respectively, and

then mixed 1 part of this resin with 5 parts of rosin ester and 0.3 part of spermaceti wax in 22 parts of toluene. Cetyl alcohol ( $\text{CH}_2-(\text{CH}_2)_{11}-\text{CH}_2\text{OH}$ ), the hydrolytic product of spermaceti wax, may also be incorporated into the rosin-modified glycerol phthalate.<sup>74</sup>

#### FURTHER MODIFICATION OF NATURAL RESIN ALKYDS

Bruson<sup>74</sup> has developed a process of esterifying rosin or other natural resins with glycerol and the straight-chain aliphatic dibasic acids such as adipic acid and higher homologues. The products are unusually tough and flexible, and maintain their flexibility down to  $-5^\circ\text{C}$ . They are compatible with cellulose esters. An example of this variety is the resin produced by heating 30 parts of rosin with 15 parts of sebacic acid and 5 parts of glycerol to  $200^\circ\text{C}$ ., finally raising the temperature to  $260^\circ\text{C}$ . Increase in the proportion of colophony increases the hardness. A similar composition, but containing 15 parts of glycerol, has been cited as giving a transparent, flexible and very elastic layer useful for photographic films or as a coating composition for leather, fabrics and rubber.<sup>75</sup> The resin derived from 95 parts of glycerol, 150 parts of rosin and 148 parts of adipic acid at  $280^\circ\text{C}$ . has been described by Sellet<sup>76</sup> as useful for paint, varnish and lacquer production.

Bruson<sup>77</sup> has also made application of the high-melting relatively insoluble and non-volatile benzophenone polycarboxylic acids with regard to resin formation, and has obtained very hard, water-resisting products of high melting point. The ketonic acids, especially benzophenone-2,4'-dicarboxylic acid, appear to be adaptable for this purpose. Seventy-five grams of benzophenone dicarboxylic acid were heated with 150 grams of rosin and 35 grams of glycerol to  $250^\circ\text{C}$ . for 4.5 hours to yield a benzene-soluble resin which melted at  $120$ - $130^\circ\text{C}$ . Darkening of the product may be avoided by allowing the esterification to take place in a nitrogen atmosphere. Related acids, such as 2,2'-dinaphthyl-1,1'-dicarboxylic acid, or 2,2'-di(biphenylketone)dicarboxylic acid, or tri- or tetrabasic benzophenone carboxylic acids give resins of similar properties. When 238 grams of dihydroxydiphenylmethane are heated with 123 grams of glycerol, a soft, colorless, sticky, partially esterified compound is formed. Subsequent reaction with 600 grams of rosin at  $290^\circ\text{C}$ . yields a clear, brittle resin soluble in fatty oils, esters, acetone and benzene.<sup>78</sup>

A rust-preventing paint can be produced by mixing rosin-modified glycerol phthalate with oils and pigments.<sup>79</sup> The clear resin (softening point  $85^\circ\text{C}$ .) is prepared by treating colophony with glycerol and then condensing with phthalic anhydride at  $250^\circ\text{C}$ .<sup>80</sup>

The co-esterification of phthalic (or other polybasic) acid and resin acids, in the form of colophony, rosin oils or abietic acid, with glycerol has also been applied by Yeates<sup>81</sup> to the production of hard, high-melting resins soluble in lacquer

solvents. Fatty acids from drying oils (linseed or tung oil) or from non-drying oils (oleic or stearic acids) may also be incorporated. When the quantity of glycerol employed is less than the chemical equivalent, inorganic basic materials may be added, if desired, to lower the acid number. A modification of the method lies in condensing a polybasic acid, together with an acid resin, with an excess of a polyhydric alcohol in the presence of cyclohexanol or methyl cyclohexanol.<sup>82</sup>

Durr<sup>83</sup> modified the process of co-esterification of glycerol, phthalic anhydride and natural resins and obtained a product of acid number 2-4 which may be heated indefinitely at 250° without becoming insoluble. When pulverized, the resin is a white- to brown-colored powder, very readily soluble in esters and in the usual cellulose lacquer solvents. The method consists in heating glycerol with phthalic acid and with natural resin, the total amount of acid taken being insufficient to esterify the glycerol completely. A resin of this nature is produced by taking 285 parts of phthalic anhydride and 200 parts of colophony with 240 parts of glycerol and heating gradually for 15-20 hours until the temperature reaches 260°C., then maintaining the melt at this temperature for 2 hours. The product melts at 105-120°C., as measured by its Ubbelohde dropping point. By heating a similar mixture to 290°C., a resin of Ubbelohde dropping point 130-138°C. is obtained.

Another process developed by Durr<sup>84</sup> consists in condensing a natural resin with glycerol, or of already formed resin esters, with previously formed glycerol phthalate resins. Condensation takes place above 200°C., the entire mixture becoming soluble in ethyl acetate, and yielding products stated to be analogous to, but not identical with, those formed by simultaneous esterification. An example cited is as follows. To 100 grams of colophony at 250°C. are added 100 grams of Congo gum and 4 grams of glycerol, the whole being heated until limpid. The resin ester so made is then introduced at 170°C. into a product made from 200 grams of glycerol and 285 grams of phthalic anhydride, finally heating for 4 hours at 260°C. The final product is soluble in esters and in mixed solvents.

Synthetic resins useful in heat-resistant molded articles or as cements for mica and similar materials, are produced by the reaction of Congo resin and a polybasic acid with polyhydric alcohols.<sup>85</sup> By heating to 230°C. 1000 grams of Congo copal, 247 grams of phthalic anhydride and 203 grams of glycerol, a resin is obtained which may either be dissolved in benzene or toluene or mixed with a filler and molded. Substitution of rosin for one-half of the Congo gives a more fusible, brittle, quick-setting product. The use of 920 grams of rosin with 740 grams of phthalic anhydride and 420 grams of glycerol yields a hard, tough resin which hardens less rapidly.

The low degree of resistance to water, which frequently constitutes a disadvantage to the use of glycerol phthalate or modified glycerol phthalate resins, is said to be overcome by the incorporation of shellac.<sup>86</sup> The process may be applied either to the initial soluble stage of the polybasic acid-polyhydric alcohol condensation, to the intermediate insoluble stage or even to the final infusible condensation product. The shellac may be dissolved in the same solvent, or powdered and intimately mixed in the case of hot-molding compositions.<sup>87</sup> The products, con-

taining about one-half of their weight of shellac, are water-resistant and may replace shellac for many purposes. Shellac may also be incorporated into a natural rosin-modified alkyd in the presence of zinc oxide.<sup>88</sup>

Useful conversion products have been obtained by reacting natural resins and their esters with phenols in the presence of boron fluoride or hydrogen chloride.<sup>89</sup> The method has been extended to alkyd resins modified with natural resin acids. Alternatively, the natural resins or natural-resin-alkyd combinations may be treated alone in inert solvents with volatile halides, such as aluminum, titanium or tin chlorides.<sup>90</sup> Another modification consists in dissolving a natural resin in an aromatic hydrocarbon and treating the solution with aluminum chloride. The product can be incorporated in alkyd resins.<sup>91</sup>

which may be used as a flexible cement (U. S. P. 1,999,097, Apr. 23, 1935, to Continental Diamond Fibre Co.) or which may be rendered insoluble and infusible by the application of heat and can be employed in the production of molded articles or electrical insulation (U. ## Chapter 44

### Modified Alkyd Resins II. Use of Drying Oils and Acids

A distinct class of modified polyhydric alcohol-polybasic acid resins includes those containing a drying oil component. That is, a monobasic drying oil acid (e.g., linoleic acid) is embodied in the molecule to yield a resin possessing properties that differ from those of other alkyd resins.<sup>1</sup>

Solutions of the different alkyd resins thus far described produce films which at ordinary temperatures retain for a long time the properties of the original resin, and which may, or may not, be hardened by heat. Alkyd resins modified by the addition of certain unsaturated monobasic acids form films which harden rapidly at ordinary temperatures in the same way as drying oils or oil varnishes. The hardening of the film is caused principally by aerial oxygen and is catalyzed by the addition of compounds of lead, cobalt and manganese. The property of hardening at ordinary temperatures differentiates these resins as a class from those that do not undergo this change. Kienle and Ferguson<sup>2</sup> showed this distinction by classifying them as oxygen-convertible resins in contrast to those, such as phthalic glyceride and alkyd resins modified by adding only a small amount of monobasic acid, which require heat to harden them (heat-convertible resins), and those that do not harden under heat, such as the resin from phthalic anhydride and glycol or a phthalic-glyceride resin modified by adding a high proportion of a non-drying acid (non-convertible resins).

Oxidizing alkyds are formed by a deep-seated reaction between the raw materials, which brings the drying oil component into chemical combination with the resin-molecule. If —G— represents a glycerol molecule with the three hydrogen atoms of the hydroxyl groups replaced,

—P— represents the phthalyl radical,

<sup>1</sup> All resins containing a polyhydric alcohol and a polybasic acid are called "alkyd" resins, even if they contain one or more monobasic acids or monohydric alcohols. For purposes of classification, however, the simple term alkyd resin is generally used to designate two-component resins, and when other reactants are added, the products are usually referred to as modified alkyd resins.

<sup>2</sup> R. H. Kienle and C. S. Ferguson, *Ind. Eng. Chem.*, 1929, 21, 349. See also H. H. Morgan, *J. Oil Colour Chem. Assoc.*, 1932, 15, 106; *Chem. Abs.*, 1932, 26, 3941; *Chem. Age (London)*, 1932, 26 (664), 256.

and D— represents the radical of a drying oil acid

then the molecular structure of the resin may be represented in a more or less idealistic manner thus:

Of course, this applies only when equimolecular quantities of the reactants are used. If less of the drying oil component (*D*) is used, more of the glyceryl radicals (*G*) tend to unite with phthalyl (*P*), thus approaching the structure of phthalic glyceride. If more than one molecular quantity of (*D*) is used, more of the glyceryl groups (*G*) are combined with radicals of the drying oil acid and the structure approaches as an upper limit that of the drying oil itself,

Oxygen reacts with the unsaturated linkages of the drying oil component both additively (oxidation) and catalytically by inducing linkage between the double-bonds of the drying oil component (polymerization). This cross-linkage of the drying oil radicals may occur either, (a) in the same molecule (intramolecular oxidation and polymerization), (b) between two or more resin-molecules (intermolecular oxidation and polymerization). The latter yields infusible and more or less insoluble products by air-drying films of the resin. Oxidation may be represented in the resin molecule by  $-D-O-D-$ , and oxygen-induced polymerization by  $-D-D-$ , so that the structural formula for the final hardened resin becomes:

The result is a three-dimensional molecule of very large size.

Drying oil alkyd resins dry faster than ordinary oil varnishes. This pro-

nounced drying property is somewhat of an anomaly when these resins are compared with the behavior of other derivatives of drying oils. The free fatty acids of drying oils do not dry. They oxidize, darken and become more viscous on exposure to the air but do not form a solid film.<sup>3</sup> Also the monohydric alcohol esters do not dry.<sup>4</sup> They absorb oxygen but remain liquid. Replacing glycerol in a drying oil by ethylene glycol gives an oil which dries more slowly than the original oil and produces a softer film; however, it forms a fairly tough film on baking. The glycol ester of tung oil acids yields an oxidation product which is a dark brown, tacky gel.<sup>5</sup>

It may be noted that the simplest formula for a resin from 1 mol phthalic anhydride, 1 mol glycerol and 1 mol drying oil acid (RCOOH) may be written:

This may be looked upon as the drying oil fatty acid ester of the monohydric alcohol:

However, as mentioned above, the usual monohydric alcohol esters of drying oil acids do not dry, whereas the drying oil alkyd does. From a consideration of derivatives of drying oil acids other than the oxidizing alkyds, it might be concluded that the oxidation of drying oil acid radicals to form hard films requires a combination of glycerol and drying oil acids as is present in the natural drying oils and that any variation in this arrangement results in poor drying. The pronounced film-forming properties of this type of drying oil derivative refutes that view. Nevertheless the result is unexpected and surprising.

Besides being molecularly of a different nature, drying oil-alkyd resins also show a contrast with ordinary oil varnishes in being more durable. Films of the resins dry rapidly, have excellent adhesion and are tough and flexible. Scheiber<sup>6</sup> has stated that the future of oil varnishes lies in the further development of the alkyd resin-oil combinations.

#### PRODUCTION OF DRYING OIL RESINS

Drying oil fatty acid radicals may be incorporated with the alkyd resin base in several ways. The free fatty acids obtained by hydrolysis of drying oils are most commonly used, and, when mixed with phthalic anhydride and glycerol, form an oily layer on top of the heated reaction mixture with which it gradually

<sup>3</sup> See R. S. Morrell and H. R. Wood, "The Chemistry of Drying Oils," D. Van Nostrand Co., New York, 1924, 21, 27.

<sup>5</sup> A. D. Miller and E. Claxton, *Ind. Eng. Chem.*, 1928, 20, 43. See also B. D. Thurman and W. R. Crandall, *ibid.*, 1928, 20, 1390.

<sup>6</sup> J. Scheiber, *Farben u. Lack*, 1932, 55, 73; 1934, 576, 330; *Chem. Abs.*, 1932, 26, 2331; 1934, 28, 6325.

(more rapidly when stirred) reacts to form a homogeneous melt. Sometimes it is possible to use the drying oils themselves, but on account of the immiscibility of drying oils and phthalic glyceride, the extreme slowness of reaction and the danger of gelatinization, it is usually\* advisable to modify the drying oil in some way first. This can be done by preheating the oil with glycerol or with the polybasic acid, or the glycerol can be modified to form ethers and esters, or be replaced by a glycol. Other ways of incorporating drying oils consist of mixing them with some of the drying oil acids or with a natural resin which acts as a flux and facilitates combination.

#### USE OF DRYING OIL FATTY ACIDS

Kienle<sup>†</sup> was the first to prepare a drying oil resin. He gradually heated a mixture of 92 parts by weight of glycerol and 296 parts of phthalic anhydride. When the temperature had reached 160°C. and a clear solution had formed, he introduced 140 parts of the fatty acid derived from a drying oil and an additional 74 parts of phthalic anhydride. Heating was continued at around 200°C. until frothing had ceased and a clear liquid had formed. The resin may also be made in a one-stage process by heating the entire mixture until the resin has formed, the correct degree of resinification being quickly determined by the stringing out of the product when it is allowed to fall in drops at a temperature of about 180°C. Resins of this type are soluble in acetone, alcohol-benzene mixtures, coal tar hydrocarbons, acetone oil, butyl acetate, butyl alcohol, ethyl lactate, glycol diacetate, glycol, glycol ethers, benzyl acetate, diethyl phthalate and triacetin. Upon air drying, the resin becomes hard, insoluble and infusible.

Weber<sup>‡</sup> found use for the fatty acids of soya bean oil. He heated a mixture of 94 parts of glycerol, 160 parts of phthalic anhydride and 80 parts of soya bean oil acids to a temperature of 265°C. and obtained a somewhat dark resin softening at 71°C. and having an acid number of 17. This resin was soluble in butyl acetate and butyl alcohol and easily miscible with nitrocellulose.

The fatty acids derived from walnut oil were employed by Bradley<sup>§</sup> in proportions of from 20 to 60 per cent by weight of the total mixture. Two hundred and thirty parts of the walnut oil fatty acids (which may be thickened by preheating), 148 parts of phthalic anhydride and 110 parts of glycerol were gradually heated (40 minutes) to 260°C. and the mixture held at from 270-290°C. for an additional 30 minutes. The resin is soluble in the ordinary paint and lacquer solvents and produces a harder and more durable film after drying; it may also be baked to a higher temperature with no material amount of discoloration or darkening; this allows both a longer baking period and a higher temperature. The finished product does not discolor with time. Lead oxide can be added to the oil-modified alkyd resin. Phthalic acid, 46.31 parts, 30.96 parts of linseed oil acids and 22.73 parts of glycerol are heated at 200°C. for 3 hours and allowed to cool to 170°C. Then about 10 per cent by weight of litharge is incorporated while the temperature is

\* R. H. Kienle, U. S. P. 1,893,873, Jan. 10, 1933, to General Electric Co.; *Chem. Abs.*, 1933, 27, 2319. British P. 284,349, 1927, to British Thomson-Houston Co., Ltd.; *Chem. Abs.*, 1928, 22, 4844. French P. 654,175, 1928, to Compagnie française Thomson-Houston; *Chem. Abs.*, 1929, 23, 3332. Canadian P. 292,344, 1929, to Canadian General Electric Co., Ltd. Belgian P. 654,175, 1928, to La Société d'Electricité et de Mécanique. The Kienle Patent is one of a group of patents formerly involved in a controversy between General Electric Co., E. I. du Pont de Nemours Co., American Cyanamid Co. and Ellis-Foster Co. Arrangements were subsequently made looking to a cessation of hostilities. Later, a suit was brought by General Electric Co. against Paramet Chemical Co. of Brooklyn for infringement of this patent (U. S. District Court, Eastern Dist. of N. Y., Equity No. 7192), *Ind. Eng. Chem., News Ed.*, 1935, 13, 24; *Paint, Oil, Chem. Rev.*, 1935, 16. In this case the patent was declared invalid. See *Ind. Eng. Chem., News Ed.*, 1935, 13, 214.

† H. M. Weber, U. S. P. 1,690,515, Nov. 6, 1928, to Ellis-Foster Co.; *Chem. Abs.*, 1929, 23, 513.

maintained at 170°C. The mixture is thinned with 150 parts of solvent naphtha and centrifuged to remove excess litharge and other impurities.<sup>10</sup>

Dawson<sup>11</sup> made a drying oil resin by using drying oil fatty acids but carried out the reaction in the presence of a small amount of concentrated sulphuric acid. The resin obtained in this way becomes hard and insoluble more quickly than without the acid. He added 10 cc. of concentrated acid to a mixture of 92 parts of glycerol and 200 parts of phthalic anhydride, and heated the mass to about 120°C. At this point much foaming occurs, water vapor and sulphur dioxide are given off and the mixture turns brown. After the rather violent reaction has subsided, about 70 parts of eleostearic acid (from tung oil) are added. This acid forms a distinct upper layer but dissolves as heating is continued. The product is a dark red mass, soluble in coal-tar hydrocarbons and in esters. It forms an adherent, water-resistant coating when applied to metals. Baking the coating for 30 minutes at about 210°C. causes it to harden. Scheiber<sup>12</sup> found that about 1 per cent of benzidine, diphenylamine or phenylenediamine facilitates the combination of drying oil fatty acids with phthalic anhydride and glycerol.

Resins of lighter color can be made by carrying out the reaction in the presence of an inert gas. Ninety-two parts by weight of glycerol, 148 parts of phthalic anhydride and 298 parts of linseed oil fatty acids, heated in an atmosphere of carbon dioxide to a temperature of 220°C. and held at this point for about 7 hours, produce a soluble, light-colored resin which hardens by oxidation. The addition of metallic driers accelerates oxidation and yields quick-drying varnishes whose films harden in about an hour.<sup>13</sup> Another related resin is obtained by heating 176 parts of glycerol, 288 parts of phthalic anhydride, 402 parts of linseed oil acids and 134 parts tung oil acids. This resin is dissolved in a hydrocarbon solvent and lithopone is ground into the solution to form an enamel for printing linoleum. The coating is hardened by drying at about 60°C. for 30 hours.<sup>14</sup> A further modification involves the use of glycol, phthalic anhydride and tung oil acids.<sup>15</sup> Zinc oxide and para toner may be incorporated to form a coating composition.

Bradley<sup>16</sup> heated a mixture containing 100 parts of glycerol, 160 parts of phthalic anhydride and 110 parts of linseed oil fatty acids at 230-250°C. for about an hour, or until a sample on cooling was non-sticky. A stream of carbon dioxide or nitrogen was passed through during the heating. The resin after cooling was thinned with solvent naphtha to a 40 per cent solution. The addition of 1 per cent liquid cobalt drier to this solution results in the formation of a light-colored, quick-drying varnish. When the film is baked a wrinkled finish is obtained. Linseed oil fatty acids which have been distilled under reduced pressure yield a light-

colored resin with glycerol and phthalic anhydride especially if the reaction is carried out in the presence of carbon dioxide.<sup>17</sup>

The solubility of linseed oil fatty acid resins in hydrocarbons increases in proportion to the amount of fatty acid. The resin made from 2 parts (by weight) of phthalic anhydride and 1 part of glycerol in the main is soluble only in alcoholic and ketonic solvents. If to this resin are added (A) 1 part, (B) 2 parts or (C) 4 or more parts of linseed oil fatty acids, the solubility in hydrocarbons progressively increases. (A) is partially soluble in coal-tar hydrocarbons and soluble in alcoholic toluene; (B) is soluble in coal-tar hydrocarbons; and (C) is soluble in petroleum hydrocarbons. The same solubility relationship holds when all the ingredients are heated simultaneously. Amieva<sup>18</sup> reported that resins containing enough linseed oil fatty acids to render them soluble in petroleum hydrocarbons dry faster when made by a modified two-stage process. He heated a mixture containing 2 parts of phthalic anhydride, 2 parts of glycerol and 4 parts of linseed oil fatty acids at about 200°C. for 6 hours and then added 2 parts more of phthalic anhydride. After heating for 6 hours longer the rubbery resin is easily soluble in petroleum hydrocarbons to give a solution which, with the addition of a small amount of liquid driers, forms a hard tough film in from 4 to 6 hours.

A higher temperature and a correspondingly shorter heating can also be used. Hopkins<sup>19</sup> heated a mixture of 171 parts of glycerol, 248 parts of phthalic anhydride, 490 parts of linseed oil acids and 164 parts of tung oil acids at 300°C. for 2 hours. The soft and sticky mass thus obtained can be mixed with ground cork and pigments and sheeted on a burlap backing to form a floor covering. Drying of the composition is carried out for several days at a temperature of about 100°C.

When raw tung oil is exposed to light in the presence of a trace of iodine or of sulphur, a solid modification, known as the  $\beta$ -form, is obtained.<sup>20</sup> Treatment with acetone and centrifuging eliminates the catalyst and the liquid oily residue. Saponification of the oily solid glyceride and neutralization yields the free  $\beta$ -eleostearic acid that can be heated with glycerol and phthalic anhydride to form a resin which dries faster than those containing the acids of other drying oils.<sup>21</sup>

When the acids of ordinary raw drying oils are used, the resin film is apt to be soft during the initial drying period but more brittle when completely dried. Pieper<sup>22</sup> sought to overcome this by substituting an oxidized fatty acid which tends to reduce the hardening effect of aging. That is, brittleness through oxidation of the film does not occur, since the drying oil acid is already more or less completely oxidized before it is combined. He heated a drying oil acid at 60-82°C. and passed air through it for 8 to 16 hours, or until it had become thoroughly oxidized. By heating 125 parts of the solid acid with the resin made from 50

<sup>20</sup> A. W. Thomas and J. C. Thomson (*J.A.C.S.*, 1934, 56, 898) have recently given an improved method for the isolation of the  $\alpha$ - and  $\beta$ -eleostearic acids. A spectroscopic study of the eleostearic acids by A. Dingwell and J. C. Thomson (*J.A.C.S.*, 1934, 56, 890) has shown that the absorption bands of the  $\alpha$ - and  $\beta$ -eleostearic acids are very similar yet differences appear which enable the acids to be readily identified by this means. Even though light does have a profound effect on the acids, no difficulty was experienced in identification by this procedure. A stronger light source, however, produced a decided change in the structure of the  $\alpha$ -eleostearic acid.

parts glycerol and 80 parts phthalic anhydride, immediate solution occurs, and the temperature is taken to 200°C. where it is held until the product has the right consistency. This resin is soluble and forms permanently flexible films.

Burke and Hopkins<sup>22</sup> used pentaerythritol instead of glycerol as the polyhydric alcohol. One formula includes 0.75 mol pentaerythritol, 1 mol phthalic anhydride and 1 mol linseed oil acids, the mixture being heated between 180° and 265°C. until foaming has ceased. Pentaerythritol resins dry more rapidly than those containing glycerol and form harder and more print-resistant films. Sorbitol,<sup>23</sup> or a mixture of sorbitol and a lower polyhydric alcohol, has also been suggested. The resin obtained from tung oil fatty acids can be hardened by heating with sulphur and the rubber-like mass thus formed may be mixed with waxes to form a floor-waxing composition. Quebrachitol has also been condensed with fatty acids of drying oils.<sup>24</sup>

The drying oil resins containing glycerol are fast-drying but the dried films are somewhat sensitive to washing with alkalis. Pieper<sup>25</sup> asserted that higher alkali-resistance is obtained when glycols are used with glycerol. This can be accounted for possibly by a higher degree of esterification with glycols in comparison with glycerol. Pieper mixed 35 parts of ethylene glycol, 3.5 to 7.5 parts of diethylene glycol, 8 to 13 parts of glycerol, 105 parts of phthalic anhydride and 10 to 20 parts of drying oil acids and heated the mass to about 220°C., just under the point of gelation. This formula utilizes only enough drying oil component to make the film flexible without imparting tackiness. The resin is soluble in the usual hydrocarbon, ester and glycol ether solvents and may be air-dried to form a film which can be washed with mild alkalis. Sherburne<sup>26a</sup> also used a mixture of glycol and glycerol. A resin was made by first heating 294 parts phthalic anhydride, 31 parts ethylene glycol, 59 parts succinic acid and 72 parts linseed oil fatty acids at 180-190°C. for 30 minutes and subsequently adding 127 parts glycerol and heating until the gel time at 200°C. by hot-plate test was 30-40 seconds. The resin becomes brittle on prolonged baking but is flexible and oil-resistant when baked for ½ hour at 100°C. Recommended uses are as a leather impregnant and as a coating for rubber and cloth.

The resin made by heating 1 mol each of phthalic anhydride, linoleic acid and glycerol can be treated with 5 per cent of sulphur chloride at 160°C. to give a product whose solutions are somewhat more viscous than those of the unsulphured resin and which dry more rapidly to films resistant to washing with sodium carbonate solutions.<sup>27</sup>

Bruson,<sup>28</sup> as stated, has used benzophenone-2,4'-dicarboxylic acid instead of phthalic anhydride for making drying oil resins. The principal advantages of this acid over phthalic anhydride are stated to be that it does not sublime during the heating operation, it has a higher melting point, it produces resins which do not soften as easily when warmed and the resin films show less solvent retention and therefore appear to dry faster. Bruson made a benzene-soluble resin by heating, for 4 hours at 250°C., a mixture of 135 g. benzophenone-2,4'-dicarboxylic

acid, 46 g. glycerol and 149 g. linseed oil fatty acids. Both isophthalic acid (benzene-m-dicarboxylic acid) and terephthalic acid (benzene-p-dicarboxylic acid) react with glycerol and linseed oil acids.<sup>29</sup> Rosenblum<sup>30</sup> replaced part of the phthalic anhydride by maleic acid and obtained light-colored resins from glycerol and drying oil acids.

Rubberseed oil, which by itself has a high acid value and poor drying properties, may be hydrolyzed and its hydrolytic products when incorporated in an alkyd resin give a cheap resin base which yields a tough film.<sup>30</sup> Rubberseed oil itself may be admixed,<sup>31</sup> as in the use of 6.75 parts of phthalic anhydride, 4.3 parts of 95 per cent glycerol, 2.55 parts of rubberseed oil and 3.2 parts of rubberseed oil acids, which are first heated at 175°C. and then finally at a temperature of 250°C. but avoiding gelation. The products are soluble in hydrocarbons, alcohols and esters.

#### USE OF DRYING OILS

Drying oils cannot be blended with phthalic glyceride by merely mixing in a common solvent, or by adding the oil to the fused resin. When a drying oil is heated with a mixture of phthalic anhydride and glycerol, combination of the oil occurs so slowly that the phthalic glyceride usually gels before all the oil has reacted. If glycol is used instead of glycerol a homogeneous resin is readily formed but its siccative properties are poor. To use drying oils and glycerol, the reaction is best carried out in the presence of a high-boiling liquid or by heating in an autoclave at a high temperature. However, glycerol may be first modified and the resin obtained by heating the drying oil with phthalic anhydride and the chemically modified glycerol.

Weber<sup>32</sup> heated a mixture of 94 parts of glycerol, 160 parts of phthalic anhydride and 80 parts of tung oil at a temperature of 235°C. in a vessel fitted with a short air-condenser. The product was a dark-yellow, hard and brittle resin containing a small amount of free oil. It had a softening point of 73°C. and an acid number of 56. This resin was soluble in a mixture of butyl acetate and butyl alcohol and was compatible with nitrocellulose in all proportions.

Combination of a drying oil with phthalic glyceride in any proportion can be accomplished by heating the two in the presence of a high-boiling solvent (benzyl benzoate, benzyl acetate, nitrobenzene, toluidine, benzyl alcohol, cresol, aniline, glycol diacetate, phenylhydrazine or o-cresyl benzoate). For example, when tung oil is added to a solution of phthalic glyceride in benzyl benzoate and heated for a long time at 200°C., the oil gradually thickens and finally disperses in the resin. Upon removal of the solvent by distillation, a sticky, viscous mass (a product of the resin and drying oil) is obtained.<sup>33</sup>

Monohydric alcohols also help to unite drying oils with glycerol and phthalic anhydride. The reaction can be carried out in the presence of a hydrocarbon or ester solvent, although the reaction occurs more rapidly if an excess of the alcohol is used. Glycerol, phthalic anhydride, tung oil and an alcoholic solvent (butyl alcohol, cyclohexanol) or glycol ethers or ethyl lactate are heated for about 20 hours

under a reflux condenser. The resin solution thus formed can be used as a varnish.<sup>34</sup>

If glycerol is first chemically modified, as by forming a monobasic acid mono-glyceride, a drying oil reacts readily with the modified glycerol and phthalic anhydride to yield a resin. The increased reactivity of the oil is possibly to be ascribed to the fact that a monoglyceride can be considered a glycol which retards gelatinization and allows the oil time to combine. Moreover, the monoglyceride is more soluble in the oil than glycerol and the reaction occurs in the liquid phase rather than at the interface between the oil and phthalic glyceride. Morgan and Drummond<sup>35</sup> heated phthalic anhydride, tung oil and glycerol monobenzoate at 220-230°C.  $\alpha$ -Chlorohydrin can be substituted. The reaction product of glycerol with formaldehyde,<sup>36</sup> when heated with phthalic anhydride and tung or linseed oil is stated to yield a homogeneous resin. Varnishes prepared from such products dry rapidly in the air after the addition of cobalt linoleate. Linseed oil is more easily incorporated than tung oil.

Adams<sup>37</sup> effected combination of a drying oil with polybasic acid-polyhydric alcohol resins by heating them together in an autoclave until dispersion was complete. Since no loss of volatile matter can take place, combination of the oil and resin occurs by re-esterification and the formation of a mixed glyceride. A solvent may be added to the initial mixture, and instead of phthalic glyceride, the separate ingredients glycerol and phthalic anhydride can be used. The mixture is heated in the autoclave at temperatures between 190° and 230°C. for about 5 hours. The product can be dissolved and used as a baking varnish but does not air-dry; it can be made to do so satisfactorily by heating with a small amount of glycerol. Kienle<sup>38</sup> added 5 per cent of glycerol to the drying oil resin formed by autoclaving a mixture of 70 parts phthalic glyceride and 30 parts of linseed oil for 5 hours at 220°C. This product is heated in an open vessel at 240-260°C. until a drop, placed on a hot-plate at 200°C., gels in about 2 minutes, after which it is thinned with a mixture of toluene and solvent naphtha. This varnish dries tack-free in about 15 hours.

A two-stage process<sup>39</sup> has been used to overcome the risk of gelation which may occur with short-oil resins, that is, those resins in which there is less oil than resin. Thirty-one parts of glycerol, 74 parts of phthalic anhydride and 45 parts of bleached menhaden oil are heated in an enamelled autoclave for 4 hours at 240°C.; the heating is then continued at 193°C. in an open vessel and the water of esterification is driven off.

Bradley<sup>40</sup> first makes up what he terms a "synthetic flux" consisting of the reaction product of diethylene glycol, phthalic anhydride and tung (or linseed) oil and then heats this flux with glycerol and phthalic anhydride until the whole mass is homogeneous.

Baird, Hill and Walker<sup>41</sup> heated a resin made from glycerol, phthalic anhydride

and oleic acid and added linseed oil slowly to the melt. A clear product is obtained after heating for about 2 hours at 230°C. The resin from linseed oil acids, phthalic anhydride and glycerol can be combined with linseed oil in the same way. Baird and Walker<sup>42</sup> have extended this method to first incorporating glycerol, phthalic anhydride and castor oil by heat and then adding with further heat a non-hydroxylated oil such as tung or linseed.

Castor oil is a non-drying oil. It is hydroxylated and differs from other vegetable oils in its ease of incorporation into alkyd resins.<sup>43</sup> A homogeneous product for varnishes is made by the destructive distillation of castor oil<sup>44</sup> until the residue is from 60-80 per cent of its original weight. The residue is esterified with glycerol and condensed with phthalic anhydride.<sup>45</sup> Heating the castor oil under reduced pressure yields lighter-colored products. The same method has been applied to mixtures of castor oil and vegetable drying oils having an iodine value above 100.<sup>46</sup>

Heck<sup>47</sup> vacuum-distilled castor oil at a pressure of 30 mm. and at a temperature of 260-270°C. and obtained essentially 9,11-octadecadiene-1-acid. This acid is heated with glycerol and phthalic anhydride at 180-230°C. until a resin is obtained which is non-tacky and soluble in benzene, toluene and coal-tar oils.

Modified polyhydric alcohol-polybasic acid resins containing a sufficient amount (usually over 50 per cent) of monobasic acid are miscible with drying oils and the resin-oil solution can be condensed by further heating. This allows the preparation of resins containing an increased amount of siccative component.

Adams<sup>48</sup> incorporated more drying oil in a finished resin to make a more flexible and adhesive cementing composition. A linseed-phthalic glyceride resin is heated until a test sample hardens in 1.5 minutes at 200°C., whereupon a small amount of bodied linseed oil is added and the mixture heated until it is homogeneous.

#### USE OF SOLUTIONS OF DRYING OILS IN POLYBASIC ACIDS

Another method of incorporating a drying oil with phthalic glyceride consists in first preparing a solution of the oil in phthalic anhydride by heating them together. If glycerol is now slowly added it dissolves and reacts readily since the polybasic acid, being in excess, acts as a blending agent. The composite resin, formed in the mixture as glycerol is added, is also a blending agent and allows a homogeneous product to be formed. Dawson<sup>49</sup> dissolved 70 parts of linseed oil by mixing with 206 parts of molten phthalic anhydride. About 92 parts of glycerol were added to the solution and the mixture heated gradually to about 250°C. A brownish resin is obtained whose solutions form a varnish which can be dried at ordinary temperatures or baked. It can also be used in a limited way as a mold-

ing material since it is converted to the infusible state by heating at about 200°C. for an hour under a pressure of 1000 pounds per square inch.

Schlingman<sup>80</sup> observed that there is always a slight amount of water present in a drying oil and when the oil is heated an equilibrium is set up as follows:

Drying oil + water  $\rightleftharpoons$  glycerol + drying oil acids. This equilibrium is such that the amounts of glycerol and oil acids are small. In the presence of an acid such as phthalic anhydride, however, the equilibrium is disturbed on account of reaction of this acid with the glycerol formed by hydrolysis of the oil, yielding phthalic glyceride and liberating water. The water thus formed is the same in amount as originally present and it again hydrolyzes more oil to yield again more glycerol and drying oil acids in a continuing cycle. When the reaction is carried out under reflux conditions so that the water is retained in the system the mixture that finally results consists of phthalic glyceride, drying oil acids, water and any excess of phthalic anhydride (as acid) that was used. If glycerol is now added the excess acid is combined and a homogeneous resin is obtained. Schlingman carried out this process as follows: 243 g. phthalic anhydride are heated to about 270°C. in a container provided with a reflux condenser and 200 g. linseed oil are slowly added drop by drop, maintaining the temperature between 270° and 300°C. during the operation. After all the oil has been introduced, 100 g. glycerol are slowly added to the mass. The resinous product is usually formed by the time all the glycerol is in, and the final heating may be done in an open vessel to allow the escape of water. This resin contains 36.8 per cent of combined oil, but a resin containing other proportions may be made in the same manner.

#### USE OF DRYING OIL MONOGLYCERIDES

As indicated, the monoglycerides of the fatty acids of drying oils combine readily with polybasic acids to form drying oil resins. The monoglycerides may be made in several ways: (1) by heating 1 mol of the free acid with 1 mol of glycerol; (2) by heating the drying oil itself (a triglyceride) with glycerol until re-esterification occurs between the oil and glycerol or (3) enzymatic partial hydrolysis. In no case is the product a pure monoglyceride but contains some diglyceride, triglyceride and perhaps a little free glycerol. The second process of forming monoglycerides is one of alcoholysis and is accelerated by use of catalysts.<sup>81</sup>

Kienle<sup>82</sup> prepared the monoglyceride of linseed oil acids by heating the acids with a large excess of glycerol. Linseed oil can be mixed with the monoglyceride thus obtained and the subsequent addition of phthalic anhydride to the hot solution yields a drying oil resin. About 100 g. linseed fatty acids and 92 g. glycerol are heated at 200-250°C. until combination has occurred and 392 g. linseed oil are stirred in, followed by 200 g. phthalic anhydride. Heating is continued until a test drop, placed on a hot plate at about 200°C., hardens in less than 5 minutes. The drying oil can be added all at once as above, or part of the oil can be mixed with the monoglyceride and the rest added after phthalic anhydride has been introduced. Hence it is possible to incorporate practically any proportion of oil desired.

Soluble balsam-like products that dry readily in the presence of metallic driers to give flexible films are obtained from linoleic monoglyceride (monolinolein) and diglycolic acid or anhydride. Thus, 180 parts of linoleic monoglyceride and 55 parts of diglycolic anhydride are heated for 8 hours at 120-125°C.; the temperature is then raised to 160°C., and the mixture heated 8 hours longer until the acid number is about 20.<sup>55</sup>

Ott, Frick and Bernard<sup>54</sup> heated 282 parts by weight of linseed oil and 92 parts of glycefol for 3 hours at 170-180°C. in an atmosphere of carbon dioxide and then gradually increased the temperature to 230°C. After adding 148 parts of phthalic anhydride the mixture was heated 3 hours longer at 230°C. The product was a viscous, light-brown resin readily soluble in drying and non-drying oils.<sup>55</sup> In another case, 0.05 part of calcium glycerate was added to 872 parts of linseed oil and 276 parts of glycerol; the mixture was heated for 2 hours at 250-280°C., 518 parts of phthalic anhydride were introduced, and finally the temperature was raised gradually to 300°C. for an hour. The acid number of the resin thus formed was reduced to 10 by allowing a stream of nitrogen to pass through it as it cooled. The resin was a clear, pale yellow material, readily soluble in aromatic hydrocarbons, esters and ketones. When this resin is heated with about 3 per cent of sulphur, or with about 5 per cent of sulphur chloride at temperatures below 200°C. the product is soluble and forms films which are tougher, dry faster and have better adhesion than the untreated resin. Using amounts of sulphur greater than 5 per cent yields insoluble products.<sup>56</sup>

Boiled drying oils can be heated with glycerol first to facilitate their combination in a resin.<sup>57</sup> Kienle<sup>58</sup> used a boiled linseed oil obtained by heating the oil at 300°C. until it had reached the desired body. Forty parts by weight of this oil and 20 parts of glycerol are mixed and heated at about 250°C. until the originally turbid mixture becomes clear. Then 49 parts of phthalic anhydride are added and the temperature held at 235°C. until the whole melt is again homogeneous. Tung oil can be combined in a resin by this process. For example, 400 parts of tung oil are heated to 235°C., 100 parts glycerol are added gradually and the mixture is heated until clear. The addition of 243 parts of phthalic anhydride forms a tung oil resin. Lighter-colored resins which do not yellow on aging are made by this process if the oil is first bleached (by heating it to 260-290°C. in the absence of oxygen).<sup>59</sup> The linseed oil is heat-treated at 270°C. and a rapid current of carbon dioxide is bubbled through the oil for 5 hours. The viscosity of the oil increases whereas the color diminishes. The oil is cooled to 250°C., glycerol poured in and the mass agitated for 3.5 hours. Molten phthalic anhydride is added and carbon dioxide bubbled through the reactants during esterification. On the other hand, tung oil can be heated with glycerol and the partially esterified

alcohol is heated with linseed oil fatty acids. The mixed acid ester is then re-alcoholized and further esterified with phthalic anhydride.<sup>60</sup> Moore<sup>60a</sup> used a small amount of sodium hydroxide as a catalyst in forming the monoglyceride from a mixture of tung or rubber-seed oil and glycerol.

Bradley<sup>61</sup> added to the drying oil alkyds a small amount of oil-soluble phenols in order to prevent frosting. Glycerol, phthalic anhydride, tung oil fatty acids, tung oil and linseed oil fatty acids were heated to 240°C. To the hot mixture were added o-hydroxybiphenyl and tung oil which had been pre-heated to 290°C. The mixed resin, thinned with turpentine, yields a varnish which does not frost in an impure atmosphere such as is found in gas-fired baking ovens.

Instead of heating the drying oil with a polyhydric alcohol, Baird and Hill<sup>62</sup> heated it with the product formed from phthalic anhydride and an excess of glycerol. After the oil and hydroxyl-containing intermediate have combined, sufficient polybasic acid is introduced to unite with the free hydroxyl groups.

By avoiding heat and alkali in hydrolysis, both polymerization and discoloration of the oil are inhibited. Robinson<sup>63</sup> used an enzyme preparation to bring this about. The enzyme is essentially lipase and is prepared from castor beans which have been allowed to remain at 25°C. for several days to promote germination and then crushed with sand in the presence of 0.5 per cent toluene. By allowing 8 parts of the enzyme in 200 parts of water of pH 5 (buffered with phosphates) and 200 parts of alkali-refined linseed oil to stand for 30 days at 25°C. an oily layer is formed of acid number of 73. Tung oil is also partly hydrolyzed by this procedure; after 75 days, the acid number is 61. By heating to 250°C., 206 parts of the filtered partially hydrolyzed oil, 96 parts of phthalic anhydride and 42 parts of glycerol, a clear, not excessively dark resin is obtained of decidedly superior drying qualities.

#### MIXTURES OF DRYING OILS AND THEIR FATTY ACIDS

As previously mentioned, the drying oil acids are fairly easy to incorporate into a polyhydric alcohol-polybasic acid resin but the free oils (glycerides) are relatively difficult to use and call for the various modifications of procedure already noted. If the oil is mixed with some of its own fatty acids, however, combination is easier since the latter act as a blending agent. The mixtures of oil and fatty acids may include simple blends or they may be partially hydrolyzed oils. Bradley<sup>64</sup> heated a mixture of 75 parts of glycerol, 148 parts of phthalic anhydride, 85 parts of linseed oil fatty acids and 85 parts of tung oil, at a temperature of 230-250°C. for an hour and thus made a clear resin whose solutions dry rapidly.<sup>65</sup>

Heating 135 parts of benzophenone-2,4'-dicarboxylic acid and 46 parts of glycerol with 120 parts of linseed oil fatty acids and 50 parts of linseed oil at 240°C. for 4 hours yields a clear, tough resin soluble in butyl acetate, toluene and acetone.<sup>66</sup>

## USE OF NATURAL RESINS

All the drying oil resins thus far described in this chapter have been of the three-component type, polyhydric alcohol, polybasic acid and a drying oil residue. If rosin or another natural resin is used with these constituents, a harder and fairly durable resin is obtained. Rosin serves to cheapen the product and for ordinary purposes forms an acceptable additive. The addition of rosin makes incorporation of the drying oil component with the resin much easier. In the presence of sufficient rosin the fatty acids react very quickly and even glyceride oils can be combined with great ease, since it acts as a blending and fluxing agent. With sufficient drying oil (or drying oil acid) on the other hand, the alkyds will dissolve both the natural and the synthetic resins.<sup>67</sup> Tung oil and rosin with glycerol phthalate resin yields a water-resistant coating. By heating 101 parts of glycerol, 164 parts of phthalic anhydride, 140 parts of tung oil and 200 parts of rosin at 285-290°C. combination between the components is effected. Tung oil appears to combine at temperatures as low as 200-210°C.<sup>68</sup>

A resin may be made by heating 92 parts by weight of glycerol, 148 parts of phthalic anhydride, 142 parts of linseed oil acids and 175 parts of rosin at 220°C. until a test-sample is clear and tough. A stream of carbon dioxide passed through the melt during the heating produces a lighter color than when the reaction occurs in contact with air. If Congo copal is used instead of rosin, the resin is less brittle.<sup>69</sup>  $\beta$ -Eleostearic acid, glycerol, phthalic anhydride and Congo copal, heated gradually to 250°C., form a soluble resin whose solutions dry very rapidly on exposure.<sup>70</sup>

The use of a mixture of rosin and castor oil to modify a drying oil resin has been proposed by Durant.<sup>71</sup> He heated phthalic anhydride, glycerol and linseed oil acids with rosin and castor oil at 240-260°C. until the acid number of the product was below 25. This resin is convertible by further heating into an infusible, insoluble mass. The drying properties can be increased by heating with a mixture of linseed and tung oil. Durant and Strutchfield<sup>72</sup> have further incorporated dibasic aliphatic acids. Phthalic anhydride, glycerol, succinic acid, ethylene glycol, rosin and tung oil are heated to 250°C. The oil-modified alkyd is soluble in acetone, cellosolve, butyl carbitol, cellosolve acetate, ethyl acetate, furfural and toluene, and has a high dielectric value.

Burke and Hopkins<sup>73</sup> used a mixture consisting of 3 mols of pentaerythritol, 4 mols of phthalic anhydride, 2 mols of linseed oil acids and 2 mols of rosin. The ingredients are heated between 180-265°C. for 7-10 hours.

When  $\beta$ -eleostearin (obtained by the action of ultraviolet light on tung oil) is pre-heated to 500°F., it becomes soluble in high-boiling gasoline or naphtha. After heat-treatment it may be added directly to drying oils (linseed) to render them faster drying or it may be incorporated in an alkyd-resin glyceride by heat.<sup>74</sup> Another procedure for incorporating tung oil is as follows. Tung oil is first heated to 300°C. in the presence of zinc rosinate and to the heated oil is added a reaction product of glycerol, phthalic anhydride, linoleic acid and maleic acid.<sup>75</sup> By heating maleic anhydride with a dihydric alcohol and subsequently incorporating rosin a strongly acidic resin is formed. Further esterification with glycerol and drying oils and drying oil fatty acids yields a homogeneous resinous mass.<sup>76</sup>

Kienle<sup>77</sup> heated 390 parts by weight of tung oil to 280°C. and added 85 parts of glycerol gradually to the hot oil. As soon as the mixture was homogeneous he introduced 191 parts of phthalic anhydride and 120 parts of rosin and heated it further until all ingredients had combined. Schlingman<sup>78</sup> reversed the process by adding the drying oil to the heated mixture of rosin and phthalic anhydride. Then, 118 g. phthalic anhydride and 63 g. rosin are heated to 270°C. and a mixture of 92 g. linseed oil, 18 g. tung oil and 8 g. castor oil is added drop by drop. After the oils have been completely incorporated 56 g. glycerol are added and the entire mass further heated at 200°C. until clear. Baird<sup>79</sup> still further modified the process. He heated linseed (or blown linseed) oil and rosin with glycerol, in excess of the amount needed for the initial esterification, until the product was homogeneous; the excess was then neutralized with phthalic anhydride.

Drying oils can be mixed with a rosin-phthalic glyceride resin merely by adding the oil to the molten resin. If the initial resin contains sufficient rosin (about 50 per cent), solution occurs at once, but if the rosin content is lower, the mixture must be heated for a period to obtain a homogeneous product. If the oil is only dispersed in the rosin-phthalic glyceride and there is no chemical combination between the oil and the resin molecule, the drying oil alkyd solution or dispersion is more closely related to usual varnish bases. Warren, Newbound and Ward,<sup>80</sup> by heating a glycerol phthalate resin with a natural or synthetic resin for some hours, obtained a clear transparent product which readily dissolved in fatty oils under short heat treatment. The solution may be thinned to a varnish of the desired consistency by addition of acetone, turpentine or hydrocarbon solvents. In an example, 1 lb. of glycerol phthalate resin and 2 lb. of rosin are heated to 220° for 6 hours. The product may be dissolved in 2.5 lb. of linseed oil by heating to 320° for 2 minutes.

The glycerol-natural resin-phthalate modification with drying oils may be effected by heating equal weights of prepared resin and linseed oil or other drying oil in an autoclave to 210° for 6 hours, or until homogeneous.<sup>81</sup> The product is a

viscous, yellow-green fluorescent mass which may be dissolved in naphtha or other hydrocarbon solvent on warming. The filtered solution forms a varnish which dries rapidly at a high temperature (3 minutes at 300°C., 15-20 hours at 110°C.) to a film which is both flexible and of a good dielectric strength. The varnishes are responsive to the customary siccative agents.

The use of natural resins, particularly the formerly despised rosin, as an aid in the commercial production of drying-oil alkyds has proved a great boon to the coating industry, as important in its way as the revolutionary discovery of the drying-oil alkyds themselves.

## Chapter 45

### Modified Alkyd Resins

#### III. Use of Other Synthetic Resins

The modification of alkyd resins by means of other synthetic resins, and particularly by the phenol-formaldehyde products, has yielded a considerable number of plastic materials for use in the production of varnishes, coating and molding compositions. Polyhydric alcohol-polybasic acid resins possess the desirable qualities of toughness, flexibility and ready solubility in numerous organic solvents, nevertheless they harden slowly under the action of heat. This property may be partially eliminated by the addition of drying oils and drying oil acids. Another alteration is by certain additions of phenol-formaldehyde resols. Moreover, the glycerol phthalate condensation products, due to their superior flexibility, can be made to compensate for the brittleness of some of the other synthetic resins. This applies again to the phenol-aldehyde type. In general, the solubility of the modified alkyd resins varies according to the type of synthetic resin modifier.

#### MODIFICATION BY PHENOL-FORMALDEHYDE RESINS

The incorporation of alkyd resins with phenol-formaldehyde resins<sup>1</sup> is capable of yielding plastics which in certain respects have better qualities than either component individually. Resins of the first type are superior in respect to mechanical strength, toughness and resistance to shock, whereas phenol-formaldehyde resins are harder and have less tendency to stick in molding. The latter may be molded quickly and be hardened or "cured" by a relatively short heat-treatment. By mixing in judicious proportions the two resins, products are obtained which possess good mechanical properties and which are said to be capable of being molded as readily as the phenol-aldehyde resins.<sup>2</sup> An early application of the mixed resins was made by Weisberg<sup>3</sup> who found that the proportions of the two resins could be varied widely, and that fillers or coloring matter (talc, rotten stone, wood flour, asbestos, iron oxide or chromium oxide) could be incorporated. A greater proportion of filler may be used than is possible when operating with phenol-formaldehyde resins alone. The two resins may be mixed by using a mutual solvent (acetone, alcohol or ethyl acetate),<sup>4</sup> a procedure which is said to be useful when the final product is to be employed as a varnish. When no fillers are added and when the resin is fusible, the two resins may be melted together. When one or both of the resins, however, are infusible, it is more advantageous to swell the resins together with the fillers by the use of hot acetone. In addition to the use in varnish manufacture, these resins are good electrical insulators.

<sup>1</sup> See Chapters 19 and 20.

<sup>2</sup> For the oil-reactive phenolic resin combinations with alkyds which require no stoving, see H. Urieh, *Farben-Ztg.*, 1934, 25, 1994; *Brit. Chem. Abs. B.*, 1934, 1069. See also W. Krumhaar, *Fed. Paint Varnish Prod. Club. Official Digest*, 1935, 142, 15.

<sup>3</sup> L. Weisberg, U. S. P. 1,449,965, Jan. 30, 1923; to Barrett Co.; *Chem. Abs.*, 1923, 17, 1341.

<sup>4</sup> H. E. Hopkins (Canadian P. 343,339, 1934; *Chem. Abs.*, 1934, 28, 7553) has used as a solvent for phenol-formaldehyde-alkyd resins a petroleum hydrocarbon of b.p. 60-260° and having an aniline point of -5 to 10° with a dielectric value of about 15 to 25.

Hönel<sup>6</sup> has extended the process of mixing alkyds with phenol-aldehyde resins so as to include a much wider range of starting materials. For example, the initial resin may be derived by heating at 160-170°C. 100 parts of phthalic anhydride and 63 parts glycerol until an acid number of 228 is attained. To the thus-formed glycerol phthalate monoester are added 60 parts of linseed oil fatty acids and 60 parts of American rosin M and the components melted. Further, a liquid reaction product obtained from 35 parts of technical m-p-cresol and 40 parts of formaldehyde (40 volume per cent) is then stirred into the mix at 160-180°C.; a homogeneous mass results. The temperature is raised to 200°C., 120 parts of linseed oil are added slowly and the mixture is heated at 280°C. for several hours. The product is soluble in aromatic or in mixtures of aliphatic and aromatic hydrocarbons and, when incorporated with driers, forms a hard varnish. The turbidity which appears in the reacting mass when an acid number of 30 is reached can be dispersed by the addition of a small amount of glycerol. Tung oil, or its fatty acids with a corresponding amount of glycerol, may be added simultaneously with the phenol-aldehyde resin. Moreover, castor oil may be substituted for linseed oil.

A further method of preparing a varnish resin of the above type is to condense 50 parts of maleic anhydride with 50 parts of glycerol at 160°C., until a clear oily product with an acid number of about 280 is obtained. Five hundred parts of American wood rosin and 150 parts of tung oil fatty acids are melted and combined with the first product. The liquid formed by the condensation of 120 parts of cresol and 160 parts of formaldehyde is then stirred in. When the reacting mass is uniform, 50 parts of tung oil, 550 parts of linseed oil and 60 parts of glycerol are added, and the entire mixture esterified. The resulting material serves as an excellent base for varnishes. A product soluble in petroleum hydrocarbons is derived from camphoric acid, glycerol, American or French rosin and corn oil fatty acids, together with the cresol-aldehyde condensate.<sup>6</sup>

The material obtained by reacting natural with phenol-aldehyde resins may be combined with a polyhydric alcohol and a carboxylic acid.<sup>7</sup> The phenol-aldehyde condensate may be derived from 150 parts of technical m-p-cresol and 180 parts of 40 per cent formaldehyde condensed by means of alkali and then introduced into 1000 parts of melted French rosin W G. The temperature of the melt is raised to 210°C. Further, 300 parts of benzoic acid and 200 parts of glycerol are added and the final esterification is carried out at 270°C. The resulting resin has a rather low melting point, but is tough and has good adhesive qualities. It is soluble in aromatic hydrocarbons and the usual mixed nitrocellulose solvents and is compatible with nitrocellulose in all proportions.

Butyric, succinic, maleic, adipic, phthalic, camphoric or citric acid may be used in place of benzoic acid. When the phenol used is substituted in the para positions (as, for example, by treating m-cresol with sulphuryl chloride), the resin finally obtained possesses a satisfactory light-proofness. A resin of the type described above may also be combined with fatty oils by heating to 240-280°C.; such materials tend to be more soluble in petroleum hydrocarbons.

In general, when an ester is heated with a low-molecular-weight resin obtained by alkaline condensation of formaldehyde with a phenol, products for coatings, impregnating agents and binders are formed.<sup>8</sup> The polyhydric alcohol esters of mono- or polybasic acids are especially used, and the reaction is carried out in absence of solvent or dispersing agent. For the condensation with formaldehyde the

phenol should have at least one of the positions in 2, 4 or 6 of the benzene nucleus substituted and the product should be capable of thermohardening.

Among the examples given by Hönel are the following: melissic palmitate (beeswax) with the liquid product from p-tertiary-amyphenol and formaldehyde; beef tallow with p-tertiary-butyl-m-cresol and formaldehyde; castor oil with p-cresol-formaldehyde; moderately boiled tung oil and linseed oil with thymol-formaldehyde; glycerol succinate-lactate with p-chlorophenol-formaldehyde; glycerol-citrate-ricinoleate-salicylate with p-cresol-formaldehyde; glycerol-phthalate-stearate with the reaction product of o-cresol and methyl ethyl ketone; and guaiacol-formaldehyde with glycerol-abietae-sebacate. Other examples include glycerol-phthalate-linoleate-abietae with butylphenol-formaldehyde; phthalic anhydride, ricinoleic acid and mannite mixture with o- and p-chloro-m-cresol; phthalic anhydride, methylcyclohexanol, glycerol with di-chloro-diphenylolpropane and formaldehyde; and citric acid and benzyl alcohol with oleic acid and glycerol. The properties of these condensation products range from that of an oily liquid to one of rubber-like consistency.

Lacquers containing phenol-formaldehyde and alkyd resins may be coated on a metal surface and, after the film has hardened, a top coat of a nitrocellulose lacquer can be applied. The alkyd resins should contain some fatty acids, especially those derived from linseed oil or castor oil. Moreover, it is advantageous to add to the initial coating an acid catalyst (sulphuric acid in alcohol) to facilitate hardening.<sup>9</sup> Both the transparency and the hardness of the finish obtained are improved by this means. A lacquer prepared from a phenol-free phenol-formaldehyde resol-modified alkyd resin dries and hardens better than one which contains free phenol. The purification of the resol may be accomplished by extracting with water. The lacquer, which consists of 12.5 parts of purified phenol-formaldehyde resol and 50 parts of a linseed oil-modified glycerol phthalate in 48 parts of butyl acetate, 16 parts of ethyl acetate, 16 parts of butanol and 7 parts of ethanol, can be brushed, sprayed or dipped, and stoved at 80-100°C.<sup>10</sup> It is also possible to heat a natural resin (rosin) with a phenol-formaldehyde product and an alkyd resin, either or both of which may be prepared *in situ*. The products have high melting points, dissolve readily in drying oils and act to form varnishes.<sup>11</sup>

Moore and Zucker<sup>12</sup> have described a somewhat similar composite resin for varnish manufacture. It is formed from glycerol phthalate-linoleate and a soluble phenol-aldehyde or phenol-ketone resin. The resins are all readily soluble in low-boiling solvents. Megson and Holmes<sup>13</sup> recommend heating the phenol and paraformaldehyde with glycerol and a polybasic acid (or its anhydride) at 185°C. for 9 hours in the absence of catalysts, to yield resins. The addition of relatively small proportions of phenol-formaldehyde to glycerol phthalate resin was found by Peterson<sup>14</sup> to accelerate the curing of the latter. The resulting material had less tendency to soften under heat. Condensation products of naphthols with aldehydes can be used with alkyd resins.<sup>15</sup>

The phenol-aldehyde-alkyd resins have been formed in the presence of boric acid to yield products which are of a sensibly neutral character, of good consistency and body and which are compatible with nitrocellulose and other cellulose esters. The resins are prepared by heating to 240°C. 148 g. of phthalic anhydride, 31 g. of boric acid and 150 g. of glycerol together with 50 g. of a phenol-formaldehyde condensate containing an organic salt of zinc. The reaction is carried out in the presence of a solvent or flux which consists of natural resins and drying or non-drying oils.<sup>16</sup>

Bielouss<sup>17</sup> has developed phenol-formaldehyde-alkyd resins with the following characteristics: solubility in drying oils with the capacity of forming quick-drying varnish; miscibility with nitrocellulose solutions to give durable lacquers for interior and exterior exposure and compatibility with other cellulose esters. Alkyd resins, when prepared in the presence of certain carboxylic acids of high molecular weight, are said to be insoluble in vegetable oils, which limits their usefulness in oil varnishes; they are, however, compatible with cellulose esters. Phenol-aldehyde resins, on the other hand, when fused with natural gums (rosin) are readily soluble in drying oils, but have a very restricted use with cellulose lacquers, due to limited compatibility, odor, brittleness of the resulting film and discoloration when exposed to the atmosphere. The combination of these two types of resin was found to give the required properties. As an example, 50 parts of phenol, 30 parts of phthalic anhydride and 65 parts of rosin were heated to 110°C., and to the molten mixture were added 17 parts of formaldehyde; heating being continued for 1 hour. The esterification of the free acids is then accomplished by adding 21 parts of glycerol and heating for 2 hours at 250°C. The acidity of the resulting resin is 11. Such a resin is soluble in oils and may be incorporated into cellulose acetate or nitrocellulose solutions with the formation of clear, durable lacquers. The order of carrying out the operation may be varied; the rosin-cresol-formaldehyde product can be esterified with glycerol at 270°C. and the resulting resin heated with the glycerol phthalate.

Bruson<sup>18</sup> has described a series of rubber-like resins, obtained by condensing a polyhydric alcohol (glycerol) with long-chain dibasic aliphatic acids (adipic,  $\text{HOOC}-(\text{CH}_2)_4-\text{COOH}$ , to sebacic acid,  $\text{HOOC}-(\text{CH}_2)_{10}-\text{COOH}$ ). When a phenol-formaldehyde resin is mixed with a solution of one of these alkyd condensation products in alcohol, acetone, ethyl or butyl acetate, homogeneous solutions result which yield tough, adherent and flexible films that retain their flexibility even when baked for a long time. Such films in either the baked or the unbaked state are insoluble in oils or hydrocarbons and may be used for coating oil-storage tanks, a case in which elasticity of the film is of prime importance.

In manufacturing a resin of this type 100 parts of a soluble Novolak phenol-formaldehyde resin are dissolved in 200 parts of alcohol and mixed with 50 parts by weight of the soluble rubbery condensation product prepared by heating glycerol with sebacic acid. A clear solution results which forms films on evaporation. Resins other than the phenol-formaldehyde may be plasticized in the same manner. These include shellac, cresol-formaldehyde resins, ketone-formaldehyde resins and condensation products of phenol with furfural as well as formaldehyde-urea resins. Instead of preparing a solution of the two resin components, the solid, hard, brittle resin may be powdered and mixed directly with the viscous rubbery condensation products in a mixer to yield a pasty mass which may be molded.

Phenol-formaldehyde condensation products containing carboxylic groups are

<sup>16</sup> I. Rosenblum, U. S. P. 1,969,761, Aug. 14, 1931; *Chem. Abs.*, 1934, 28, 6330. See I. Rosenblum, British P. 416,476, 1934; *Chem. Abs.*, 1935, 29, 1176. French P. 738,444, 1932; *Chem. Abs.*, 1933, 27, 1775.

<sup>17</sup> E. Bielouss, U. S. P. 1,866,962, July 12, 1932, to Henry A. Gardner Laboratory, Inc.; *Chem. Abs.*, 1932, 26, 4726.

<sup>18</sup> H. A. Bruson, U. S. P. 1,732,166, Nov. 25, 1930, to Resinous Products & Chemical Co.; *Brit. Chem. Abs. B*, 1931, 687.

formed in the reaction of a phenol-formaldehyde resin with a halogenated aliphatic acid (chloroacetic acid) or by the reaction of a phenoxy aliphatic acid (cresoxy-acetic acid) with formaldehyde. The product is a "resin acid," and when it or its ammonium or amine salt is heated with a polyhydric alcohol above 100°C. a hardened mass is formed. Mixed with fillers, this may be used for making laminated products.<sup>19</sup> An example is given in which an alkaline solution of a condensation product from a mixture of cresols and formaldehyde is treated with sodium chloroacetate. The resinous product is precipitated by acidifying, and is then condensed with glycerol. A resin is obtained which becomes insoluble and infusible, but which remains elastic, when heated to 150-170°C. Polyvinyl alcohol and water-soluble carbohydrates may take the place of glycerol.<sup>20</sup>

The condensation products of polybasic aliphatic acids with hydroxyalkyl ethers of polyhydric alcohols may be mixed with unhardened or incompletely hardened phenol-aldehyde condensation products and the mixture subjected to a hardening process. The products obtained are less brittle than those from the corresponding phenol-aldehyde resins alone, and may be used for making films, plastic masses and lacquers. Suitable condensation products are obtainable from succinic acid and glycerol trihydroxyethyl ether or sorbitol polyhydroxyethyl ether. Aromatic or hydroaromatic acids may be used in place of the aliphatic acid.<sup>21</sup>

A resin for cementing glass, metals and wood is prepared by heating benzoic or cinnamic acid with glycerol and cyclohexanol in the presence of phenols and aldehydes. The material obtained is dehydrated by heating under reduced pressure.<sup>22</sup> Glass sheets and sheets of cellulose or cellulose acetate compositions may be united by means of resins formed from phthalic anhydride (with succinic) and glycerol and from phenols and formaldehyde at the "A" stage of condensation, with or without further treatment with resin acids such as abietic acid. Nitrocellulose, dissolved in a solution of the mixed resins, assists cohesion.<sup>23</sup>

Xylenol-aldehyde resins have been incorporated into glycerol phthalate and into the rosin-glycerol phthalate condensation products. A mixture consisting of 61 parts of the technical xylenols, 83 parts of formalin and 2.5 parts of sodium hydroxide solution were heated to boiling for 30 minutes, cooled, the aqueous layer decanted and then reheated to 70°C. in order to clarify the solution. The xylenitic resin was then incorporated with 148 parts of rosin, 63.1 parts of phthalic anhydride and 48.4 parts of glycerol and heated to 280-290°C. for 45 minutes, followed by steaming for 1 hour at 250-260°C. The softening point of this resin was 155-160°C. and it was compatible with nitrocellulose. A solution of 20 parts of the xylenol-aldehyde modified alkyd resin and 5 parts of half-second nitrocellulose in 10 parts of butyl alcohol, 20 parts of butyl acetate and 30 parts of toluene yielded hard, brilliant films which were relatively light-stable.<sup>24</sup>

#### MODIFICATION BY PHENOL-FURFURAL RESINS

The combination of polybasic acid-polyhydric alcohol resins with furfural-phenol resins was developed by Weber.<sup>25</sup> A molding mixture is prepared by dissolving

<sup>25</sup> H. C. P. Weber, U. S. P. 1,715,888, June 4, 1928, to Westinghouse Electric & Mfg. Co.; *Chem. Abs.*, 1929, 23, 3823. British P. 233,519, 1925, to Metropolitan-Vickers Electrical Co., Ltd.; *Chem. Abs.*, 1927, 21, 2687.

10-30 parts of the phenol-furfural resin in about 10 parts of alcohol and adding a solution of 70-90 parts of the glycerol resin component dissolved in 10 parts of alcohol. Twenty parts of a filler (e.g., mica or wood flour) are incorporated and the solvent is removed by evaporation. The dried, impregnated composition is then finely ground, and may be converted into an insoluble infusible stage by molding with heat and pressure. Instead of mixing solutions of the resins, the solids may be mixed, either with or without a filler, and hot-molded as before. In cases where a varnish is required, an alcoholic solution is employed. Both the molded products and films or impregnated materials have excellent insulating properties.

The properties of the blended resin probably result from a mutual condensing action of the resins upon each other, inasmuch as the resin can be brought to the infusible stage, that is, the "C" stage much more easily than if the composition were merely a mixture of the two resins. The final product retains the good insulating and resistant properties of the alkyd resin, together with the ease of molding of phenol-furfural resins.

#### MODIFICATION BY UREA-FORMALDEHYDE RESINS

As has already been mentioned,<sup>26</sup> colorless resins are formed by condensing urea with formaldehyde. These resins harden rapidly under the influence of heat but they lack flexibility when so hardened and are only sparingly soluble in such common solvents as acetone and toluene. Hill and Walker<sup>27</sup> have employed urea-formaldehyde resins as modifying agents for the alkyd resins, and have developed in this way products which are said to harden very readily under various conditions. First, an alkyd resin is prepared by heating together 148 parts of phthalic anhydride, 62 parts of glycerol and 150 parts of castor oil at 190-200° for 45 minutes. The product is a pale yellow, tough, flexible and moderately hard resin which is soluble in ketones, esters, hydrocarbons and in hot alcoholic solvents. After dissolving 14 parts of this resin in 14 parts of butyl alcohol, and adjusting the hydrogen-ion concentration to  $10^{-6}$  by adding alcoholic caustic potash, 3 parts of urea are added. The solution is heated to dissolve the urea and then 3 parts of paraformaldehyde are added and the mixture refluxed for a short time. The resulting solution is diluted with 10 parts of solvent naphtha and traces of suspended matter are filtered off. The product is a clear, pale yellow liquid from which the resin may be isolated by vacuum evaporation at low temperatures. On baking, transparent colorless coatings are obtained which possess good adhesion, flexibility, hardness and toughness. This resin is compatible with nitrocellulose, and may be employed as a component in lacquers.

Dimethylolurea itself may be employed and thiourea may be used in place of urea. The components are said to react chemically and do not form a simple mixture. As little as 5 per cent of the urea-formaldehyde condensation product exerts a considerable modifying action on the alkyd resin. The choice of the components of the polyhydric alcohol-polybasic acid resin is controlled by the purpose for which the product is intended. When hardness in the final material is the chief consideration, an unmodified glycerol phthalate condensation product should be employed. When flexibility and light color are desired a castor oil-modified alkyd resin serves the purpose. Incorporation of a drying oil fatty acid is likely to result in a degradation of color. Small amounts of inorganic

<sup>26</sup> See Chapter 26, *et seq.*

<sup>27</sup> R. Hill and E. E. Walker, U. S. P. 1,877,130, Sept. 13, 1932, to Imperial Chem. Ind., Ltd.; *Chem. Abs.*, 1932, 27, 300. British P. 344,401, 1939; *Brit. Chem. Abs. B*, 1931, 597. German P. 594,197, 1934; *Chem. Abs.*, 1934, 28, 3603. French P. 694,181, 1930; *Chem. Abs.*, 1931, 25, 2013.

acid may be used in preparing the final product; this allows drying at room temperature.

Thus, to 100 parts of the alkyd resin (castor oil-modified, just described) dissolved in 200 parts of glycol monoethyl ether, 100 parts of dimethylolurea are added and the mixture refluxed for 30 minutes; 85 parts of methylated spirits (ethanol denatured with methanol) and 85 parts of toluene are then added. Sixty parts of the resulting lacquer are treated with 0.42 part of a 10 per cent solution of sulphuric acid dissolved in a mixture consisting of 2 parts of glycol monoethyl ether, 1 part of toluene and 1 part of methylated spirit. A lacquer of this type, containing a small amount of acid, dries rapidly at ordinary temperatures, whereas one without acid requires heat treatment for rapid hardening to take place. Besides sulphuric acid, sodium hydrogen sulphate, chlorosulphonic acid, sulphuryl chloride, hydrochloric acid, trichloroacetic acid, tartaric acid, boric acid and malic acid are effective.

Goldschmidt and Mayrhofer<sup>28</sup> have produced modified alkyd resins by adding the liquid or viscous condensation products from phthalic anhydride and polyhydric alcohols to an aqueous suspension of urea and formaldehyde. The addition is made prior to, during or after formation of a condensation product by heating in presence of 2 *N* sulphuric acid. The products can be hardened in molds at a temperature higher than normal without danger of cracking and are transparent and vitreous. The ratio of the weights of urea and phthalic anhydride must be considerably greater than unity and an acid or an alkaline condensing agent may be present. It is also possible to include a phenol in the reaction mixture in carrying out the above condensation.<sup>29</sup> Colored lacquers, made from synthetic resin compositions of glycerol phthalate-formaldehyde-urea (or -thiourea) and dyes (Cardinal Red J) may be used for producing colored electric-light bulbs. The lacquer is applied to the bulbs by dipping and the coating hardened by the normal heat of the lamp.<sup>30</sup>

Condensation of urea and formaldehyde in aqueous solution may be carried out to yield an initial product, to which is added, after concentration, a polyhydric alcohol-polybasic acid resin. The solution is further concentrated, dried *in vacuo*, and may then be molded under heat and pressure. Thiourea may be substituted for part of the urea. In the initial condensation the  $p_H$  is adjusted to between 5 and 6 by adding triethanolamine. A sufficient quantity of the alkyd resin is then added to lower the  $p_H$  to between 3.5 and 5.0.<sup>31</sup> A similar product<sup>32</sup> is obtained by adding less than 1 mol of urea to 2.25 mols of formaldehyde, the  $p_H$  of which has been adjusted to between 6 and 7 by addition of an organic base (triethanolamine). The mixture is heated under reflux until spontaneous boiling ceases, whereupon more urea is added and the product concentrated to a thick syrup by evaporation in the open. The  $p_H$  is then adjusted to 7-7.5, and thiourea added in the ratio of 1 mol to 2 mols of the remaining uncombined formaldehyde. The product is again boiled and concentrated. An alkyd resin (or other plasticizer) is added and the  $p_H$  adjusted to between 3 and 5. The product is then dried *in vacuo* and ground. Resinous condensation products from urea or its derivatives and paraformaldehyde may also be formed in presence of organic compounds such as colophony, copal, amines, in addition to the alkyd resins. Anthracene and chlorinated or nitrated naphthalenes serve as plasticizers for these products.<sup>33</sup>

Howald<sup>44</sup> has prepared a resin by reacting 1 mol of ammonium thiocyanate with 1.5-2 mols of formaldehyde, the excess formaldehyde being condensed with urea, thiourea or resorcinol during the molding operation. The resin was plasticized by a polybasic acid-polyhydric alcohol ester so prepared as to contain free carboxyl groups.

#### PHTHALIDES AS MODIFYING AGENTS

The use of phthalides as modifying agents for alkyds and other synthetic resins has been developed by Jaeger.<sup>45</sup> Phthalide<sup>46</sup> (m.p. 83°C., b.p. 290°C.), the lactone or internal ester of o-carboxybenzyl alcohol of the structure

possesses desirable softening properties when incorporated into alkyds. It is also non-corrosive, relatively non-volatile and satisfactorily withstands the temperatures required in molding. Hexahydrophthalide (b.p. 134-138°C. at 25 mm.) is a much more fluid compound than phthalide itself and is a colorless, odorless, heavy oil. Other derivatives include the mono- and disubstituted phthalides, as well as the alkylidene phthalides.

The method of using the phthalide is as follows: to 85 parts of glycerol phthalate resin, which is freshly prepared and fairly hard but not infusible, are added 15 parts of phthalide and the mixture heated to 150°C. until a homogeneous mass is obtained.

Among the polyhydric alcohols used in preparing the alkyd resin to be modified by phthalides, glycerol and glycol are of the greatest commercial importance, although others may be employed, among which are butylene glycol, mannitol and glycol propyl ether. Phthalic anhydride is the most important dicarboxylic acid, though substituted phthalic acids, sebacic or succinic acid, give similar results. Other acids, such, for example, as the monocarboxylic acids, may also be incorporated in the alkyd resin.

The following example illustrates the method of preparing a resin of this type: 1 mol of glycerol and 1 mol of phthalic anhydride are heated at 180°C. until gas evolution ceases; 1 mol of phthalide is then added and the mixture is heated at 210°C. until a test portion on a glass rod solidifies to a hard product which is not

sticky. The resin is then mixed with an equal weight of phenol-formaldehyde or phenol-furfural resin, capable of being hardened by heat, together with a wood-flour filler and a pigment. This admixture is best made by grinding in the dry state. After adding 5 per cent of dibutyl phthalate, the product is hot-molded. Products are obtained which have excellent strength and which will take a high polish.

A resin obtained from 2 mols of glycerol, 2 mols of phthalic anhydride, 1 mol of phthalide and 1 mol of benzoic acid may be incorporated with half its weight of a formaldehyde-urea or formaldehyde-urea-thiourea resin. Again, a resin containing 1.5 mols of phthalic anhydride, 1.5 mols of phthalide or ethylphthalide and 1.0 mol of the fatty acids of coconut oil, is soft and flexible. Mixed with an equal proportion of a vinyl resin and dissolved in a solvent, a solution for impregnating paper results. Other synthetic resins may also be incorporated, among which are amine drying oils of the tung oil-toluidine type, aminoketone resins, polymerized styrene or itaconic acid resins. In general the phthalide-modified resins are soluble in the solvents which will dissolve the unmodified resin as well as in additional solvents. This range of solubility adds greatly to the adaptability of these resins for coating compositions. The phthalide-modified alkyd resin in its fusible stage is soluble in alkyd resin solvents and may be blended with nitrocellulose.<sup>37</sup> An impregnating varnish is thus obtained which leaves film of excellent quality without the use of any plasticizer. Where maximum flexibility is needed, an amount of dibutyl phthalate or ethyl benzoylbenzoate equal to about 5-10 per cent of the weight of resin may be added. A soft, balsam-like resin is obtained with 1.5 mols of ethylene glycol, 1 mol of phthalic anhydride and 1 mol of phthalide or hexahydrophthalide.<sup>38</sup>

#### MISCELLANEOUS RESINS

Hovey<sup>39</sup> has tabulated the means by which alkyd resins may be made compatible with or blended with other plastic materials. Due to the many types of alkyds and to the variation in naturally occurring materials with which these resins may be used, certain minor discrepancies will occur; the table nevertheless serves as a useful guide. See page 943.

Natural or artificial rubber may be mixed with resinous esters of mono- or polybasic acids with polyhydric alcohols before vulcanization in order to increase the strength of the product. Thus, for example, acids such as abietic, phthalic or palmitic may be esterified with glycols or with ethylene oxide and the products added to the rubber in the proportion of about 2 per cent.<sup>40</sup> Coating and adhesive compositions may be manufactured from the oily polymerization products of diolefins (butadiene) polymerized without the aid of alkali metals. The oil is incorporated with synthetic resins, among which are those of the alkyd type. Cellulose ethers and esters, drying oils, natural resin, fillers and vulcanizing agents may also be added.<sup>41</sup> Addition of drying oil-modified alkyds to the lacquers prepared from chlorinated rubber improves the films.<sup>42</sup>

An adhesive for uniting celluloid to glass prepared by Ford and McCarroll<sup>43</sup> consists of polyvinyl acetate, glycerol phthalate and a plasticizer. Products used

for molding are obtained by mixing polymerized vinyl chloride and alkyd resins, preferably of the flexible type. Among the fillers which may be used are the oxides of zinc or titanium.<sup>44</sup> Polymerized acrylic acid derivatives, such as the allyl or methyl esters, are improved by the incorporation of esters of polybasic acids and polyhydric alcohols (monoacetin  $\beta$ -methoxyethyl phthalate). They are then more suitable for use in safety glass.<sup>45</sup>

Solutions of polymerized styrene and natural or synthetic resins compatible with it are used in the manufacture of varnishes. Among the resins which may be used are those of the linseed oil-alkyd type.<sup>46</sup>

Moore and Zucker<sup>47</sup> used a mixture of 35 parts of phthalic anhydride, 22.5 parts of linseed oil acids and 17.5 parts of glycerol and in addition 25 parts of cumarone resin. The latter allows the reaction to proceed without danger of gelation, thus allowing more complete interaction; it also imparts some water-resistance and lowers the acid number. Larger amounts of cumarone resin impart brittleness unless the oil content is increased.

Gardner<sup>48</sup> has found that incorporation of chlorinated biphenyl<sup>49</sup> with alkyd resins or other types of synthetic resin accelerates their speed of drying. A resin is first made by heating 100 parts of phthalic anhydride and 32 parts of glycerol to temperatures below 190°C., and to the resulting fluid mass are added with stirring 25 parts of chlorinated biphenyl (containing 50-60 per cent of chlorine).

<sup>49</sup> See Chapter 56.

The product is a light-colored resin which may be admixed with the usual varnish oils. These films dry so rapidly that successive coatings may be applied at intervals of 30 minutes. The resulting composite is then baked and is said to serve as an undercoat for nitrocellulose lacquers. A mixture of alkyd resins and chlorinated biphenyl has also been suggested for use in safety glass.<sup>60</sup>

Compositions with improved water-resistance are reported obtainable by modifying alkyd resins with ketenes.<sup>61</sup> The resin is dissolved in ethyl alcohol or acetone and the ketene added either as a gas or in solution if it is of high boiling point.

Casein plastics are usually prepared by first extruding a casein mass with approximately 20 per cent of water through a heated screw press and then hardening the extruded mass with formaldehyde. By combining casein with alkyd resins and treating with formaldehyde, a mass results which when dried and powdered can be hot-molded. The procedure is as follows: 25 parts of a castor oil-modified glycerol phthalate are added to 75 parts of water containing 2.67 parts of a 28 per cent solution of ammonium hydroxide. Seventy-five parts of casein are dissolved in 1000 parts of water and warmed at 60°C. and concentrated ammonium hydroxide added until a smooth dispersion is obtained. The solutions of casein and resin are mixed and precipitated with dilute, 25 per cent hydrochloric acid. After the precipitate has settled 200 parts of 37 per cent formaldehyde are added and the mass allowed to stand for 48 hours. It is then washed, dried, comminuted and molded.<sup>62</sup>

Protein-modified resins may be made by heating gelatin or casein with a mixture of glycerol and phthalic anhydride. For example, 35.1 parts phthalic anhydride, 14.9 parts glycerol and 10 parts gelatin are heated for about 5 hours at 200°C. until the product possesses an acid number of 65-70. The resin may be used in safety glass.<sup>63</sup> Another type of modified resin is obtained by use of simple amino acids, the hydrolytic products of proteins.<sup>64</sup>

## Chapter 46

### Alkyd Resin Salts

Under strenuous alkaline conditions the polyhydric alcohol-polybasic acid resins are completely saponified. Mild alkaline treatment, however, gives rise to products which can be used in the form of aqueous solutions or dispersions as coating, impregnating or cementing compositions and as plastic materials. The important factors in the preparation of the water-soluble alkyd resins are first the acid number of the resin and second the amount of alkali used in the neutralization. Resins of low acid number are dispersed or emulsified in the presence of alkalies. With resins of a high acid number, a small amount of alkali causes dispersion or emulsification, but a large amount of alkali, that is, equivalent to the acid number of the resin, results in the formation of a clear water solution in which the salts of the resin are soluble. The neutralization may be achieved by treating a water-insoluble resin of the glycerol phthalate type, prior to the formation of the final hard insoluble modification, with an aqueous solution of either inorganic bases (ammonium, potassium, sodium, calcium or barium hydroxide or sodium sulphide) or with organic bases (hexamethylenetetramine, toluidine or aniline).<sup>1</sup> For example, 60 parts by weight of castor oil-phthalic glyceride resin are heated to 110°C. and poured slowly, with agitation, into 200 parts of boiling water containing 6 parts of concentrated ammonium hydroxide solution. The resulting resin dispersion can be used for treating paper by brushing, flowing, spraying or dipping.

A resin of acid number 36.5 and melting at 62°C. is prepared from animal tallow fatty acids, 9 parts, phthalic anhydride, 16 parts, and glycerol, 10 parts, by heating at 245-250°C. for 1 hour. By agitating this material in water rendered slightly alkaline with potassium hydroxide, a milky emulsion forms, which when introduced into paper and dried, imparts a glossy surface to the latter.

Cottonseed-phthalic glyceride resin gives favorable results when dispersed in water containing ammonium hydroxide. A dispersion of this type was employed by the author in making a "greaseproof" paper. These compositions are also useful as cementing compositions especially in building up sheets of paper into thick board.

Resins derived from polybasic acids other than phthalic may be used, although the cottonseed-phthalic glyceride resin is outstanding in this respect because of its cheapness, the ease with which emulsification takes place and its excellent grease- and water-repellent properties. The stearic resins are harder, whereas oleic resins are inclined to be soft and somewhat sticky. Benzoic-phthalic glyceride is more difficult to emulsify with aqueous ammonium hydroxide; an aqueous medium containing 3 per cent each of ammonium hydroxide and gum arabic yields a better emulsion in this instance. Other emulsifying agents include gum tragacanth and Irish moss.

<sup>1</sup> British P. 368,997, 1930, to Ellis-Foster Co.; *Chem. Abs.*, 1933, 27, 1774. French P. 698,598, 1930; *Chem. Abs.*, 1931, 25, 3186.

Bradley<sup>2</sup> has described a related method of treating a glycerol-phthalic anhydride resin with ammonia in order to render it water-soluble. The resin itself was prepared by heating a mixture of 90 per cent glycerol, 63 parts, and phthalic anhydride, 148 parts, at 150-230°C. until, on cooling, a sample set to a resin softening at 85-100°C. and had an acid number of from 100-150. Fifty parts of this resin are then agitated with 100 parts of water and 6.5 parts of 46 per cent ammonium hydroxide until the resin has dissolved in the water to form a clear solution. This reaction may be carried out at room temperature, but takes place more quickly at an elevated temperature. Other alkalies (sodium or potassium hydroxides) and also organic bases (ethanolamines) gave similar results. By allowing the aqueous solution of the resin to flow on to tissue paper and drying at 80°C. for 10 minutes, the paper became transparent. A greatly enhanced water-resistance was imparted to the paper by treatment with a dilute solution of acetic acid before drying; the resin is rendered water-insoluble by the acid.

Other resins, derived either from polyhydric alcohols and polycarboxylic acids alone or admixed with monobasic acids, were found by Bradley to give similar results; among these may be mentioned the resins from glycerol, phthalic anhydride and linseed oil fatty acids, and from ethylene glycol and succinic acid. The aqueous solutions of resins may be used in conjunction with casein. A solution of 32 parts of casein, 160 parts of water and 8 parts of concentrated ammonia is mixed with an equal quantity of one of the resin solutions, applied to the paper and dried at 100°C. for five minutes. A homogeneous, transparent and glossy film is obtained. Its water-resistance is improved by dipping the coated paper in 40 per cent aqueous formaldehyde and drying. It has also been found that these resins may be precipitated from aqueous solutions by water-soluble polyvalent metallic compounds (barium and calcium hydroxides) and salts (alum or iron salts). These insoluble products are metallic glycerol phthalates.

Coating compositions, which form a relatively stable combination with a flattening agent such as aluminum stearate, are prepared by emulsifying with water a solution of glycerol phthalate in an organic solvent. Bentonite, soap or gelatin serve as emulsifying agents.<sup>3</sup> Ethylamine, diethylamine, triethylamine or piperidine react with alkyd resins in water to give a homogeneous solution which is capable of forming a resinous coating on a substratum.<sup>4</sup> The type of alkyd resin may be varied widely. When flexible coatings or films are required, the resin may contain castor oil, olive oil or the fatty acid radicals of such oils. Products yielding coatings which are to harden by exposure to the atmosphere contain linseed oil or linseed oil fatty acid radicals. Table 46A shows the quantities used in preparing some of these resins, together with the acid value of the product and the time in hours for which the ingredients are heated.

The molten resin is poured into the aqueous solution of the base, and stirred until a homogeneous solution results. The resin ingredient, 40 parts, may also be heated with 6.5 parts of piperidine at 60°C. for 30-40 minutes, and the product so obtained dissolved in water. The water solutions when applied to a surface give clear, hard, adherent films on stoving for 1 hour at 100°C. If the resins are treated with an alkali hydroxide or salt of a weak acid (sodium carbonate

or sodium sulphide) and dissolved in water, the films obtained by drying at 100°C. are water-soluble and may be rendered insoluble by treatment with acids.<sup>5</sup>

Coating compositions intended for baking are obtained by dissolving an alkyd resin (containing an excess of polybasic acid) in dilute ammonium hydroxide and adding enough glycerol so that the solution, when applied to an article and baked, will yield an insoluble resinous coating.<sup>5a</sup>

#### APPLICATIONS OF ALKYD RESIN EMULSIONS AND SOLUTIONS

The alkaline solutions of alkyd resins already described have been applied for stiffening and proofing felt-hat shapes.<sup>6</sup> A solution of this nature is prepared by dissolving 25 parts of the resin formed from heating 31 parts of glycol, 74 parts of phthalic anhydride and 35 parts of castor oil at 185°C. (until the product has an acid value of 95) in 100 parts of 0.39 per cent aqueous ammonia at 60-80°C., and diluting to 250 parts. The impregnated felt is dried to volatilize the ammonia. If metal hydroxides or carbonates are used for dissolving the resin, the felt should be treated with dilute acid either before or after impregnation. Textile materials, other than felt, may be impregnated with a 3 to 35 per cent aqueous solution of an alkyd resin treated with ammonia or a similar base,<sup>7</sup> and then dried or treated with a metallic salt. The latter procedure forms an insoluble derivative of the resin. The elasticity and other physical properties of the textile material are improved in this way.<sup>8</sup>

Alkyd resins have been used to render rubber adaptable to the formation of plastic compositions which are resistant to hydrocarbons. A latex is thoroughly mixed with a solution of alkyd resin in 5 per cent aqueous ammonia. Acetic acid is added and the precipitate is washed with water, dried and finally vulcanized. Rubber dispersions and alkyd resins which have been modified with drying oils or organic acids may also be utilized.<sup>9</sup> A further process for impregnating surfaces makes use of a composition consisting of an aqueous emulsion

of a resin of the alkyd type, and rubber, rubber latex or a rubber-like artificial product. The coating consists of alkyd-urea-formaldehyde resin, 11 parts, 30 parts of alkyd resin, 14 parts of solvent naphtha, 45 parts of butyl alcohol, 10 parts of rubber-substitute emulsion and 65 parts of water. The alkyd resin is prepared from 148 parts of phthalic anhydride, 62 parts of glycerol and 150 parts of castor oil at 190-200°C. To 10 parts of the castor oil-modified alkyd resin dissolved in 20 parts of glycol monoethyl ether are added 10 parts of dimethylolurea and the mixture heated. The two modified-alkyd resins are dissolved in the organic solvents, water is added to the rubber-substitute emulsion and the two solutions are mixed and passed through a colloid mill.<sup>10</sup> The emulsion thus obtained is applied by coating, dipping, spreading or spraying and is dried above 90°C. to form a pale-colored coating which has excellent flexibility, weathering properties and a semi-glossy appearance. Chloroprene can also be treated with a water-soluble salt of a glycerol phthalate resin to form an emulsion.<sup>11</sup>

#### VARIOUS APPLICATIONS

Emulsified alkyd resins can be used in the production of paints.<sup>12</sup> When glycerol, 368 parts, linoleic acid, 834 parts, and phthalic anhydride, 518 parts, are condensed together, a soft resin is formed, 100 parts of which are emulsified with 1-2 parts of the ammonium salt of diisopropyl-naphthalene-sulphonic acid. One hundred parts of bleached montan wax are then treated with 4 parts of ammonia in 100 parts of water and mixed with the aqueous emulsion of the resinous body. Finally 150 parts of red iron oxide are incorporated into the mixture. The consistency of the resulting paint may be varied within wide limits by dilution with water without altering its stability; it can therefore be applied by brushing, spraying or printing. Titanium oxide may be used in place of iron oxide and it is also possible to mix the emulsified resin with an aqueous solution containing casein, 2 parts, ammonia, 0.1 part, and chromium oxide, 100 parts. The emulsion of the alkyd resin may be mixed with 20 parts of the azo dye pigment Lithol Red [B] (prepared from diazotized 2-naphthylamine-1-sulphonic acid and  $\beta$ -naphthol) and 80 parts of chalk.

One hundred parts of a hard condensation product from 276 parts of glycerol, 278 parts of linoleic acid and 518 parts of phthalic anhydride can be dissolved in a mixture of 90 parts of toluene and 10 parts of alcohol and then admixed with an emulsion consisting of 50 parts of shellac wax saponified by aqueous ammonia, 10 parts in 240. Further incorporation of 100 parts of yellow iron hydroxide yields a paint when diluted with water prior to application.

These paints can be applied in the manufacture of waterproof wallpapers, it being possible to print by rollers several designs in rapid succession, without the colors flowing into one another. They also have a general application for rendering porous surfaces waterproof. A paint can also be prepared by adding rouge to montan wax saponified by ammonia and mixed with toluene, water and the modified alkyd resin. The modified resin may also be emulsified with an aqueous solution of casein, ammonia and a small amount of a magnesium or lead salt of a high molecular weight organic acid.<sup>13</sup> Compositions for priming or surfacing

absorbent foundations of stone or wood are furnished by the water emulsions of condensation products from glycerol or pentaerythritol and phthalic, malic or maleic acids together with linoleic or eleostearic acids.<sup>14</sup> If to the aqueous emulsion of linseed oil-modified alkyd are added small amounts of casein, ammonia and a manganese or lead salt of an organic acid, an adherent floor covering can be made.<sup>15</sup> Products obtained by the alkaline neutralization of the synthetic resins, added to make-up water, can also be used in waterproofing concrete.<sup>16</sup>

Suspensions or colloidal solutions of glycerol phthalate resins can be obtained by pulverizing the resin in the B-stage of condensation, screening off the larger particles and mixing the powder with about 10 per cent of a plastic clay, such as natural kaolin. Water is added, and the whole is stirred while being heated to its boiling point.<sup>17</sup> Paper when treated with an aqueous solution of the alkyd resin containing clay can be stacked in layers and molded under heat and pressure to form a laminated product.<sup>18</sup> Moreover, these suspensions may be utilized as adhesives or as binding agents in plastic compositions containing mica, asbestos, wood flour or ground minerals. They are useful for coating surfaces of metal or glass or for the preparation of moldings. Subsequent heat curing is employed in either case. Plastic materials are prepared by neutralizing with volatile bases the intermediate acid products formed during the reaction of polybasic acids with polyhydric alcohols. The neutral products are condensed by heating.<sup>19</sup> Alkyd resins can be combined with amino alcohols which include mono-, di- and triethanolamine, diaminopropanol, butanolamine and pentanolamine. These derivatives can be dispersed in water and the free acidic groups converted into salts. They are said to be particularly useful in making aqueous dispersions of dyes for dyeing and printing textile fibers and for dispersing lakes and pigments for use as aqueous paints.<sup>20</sup>

#### METALLIC SALTS OF RESINS

The soluble products formed from alkyd resins by treatment with aqueous alkalies yield a series of metallic derivatives when treated with solutions of metallic salts (barium or calcium chloride, cobalt nitrate or copper sulphate).<sup>21</sup> For example, on adding a 1 per cent aqueous solution of barium chloride to a 10 per cent aqueous solution of an ammonium glycerol phthalate, an insoluble barium salt is precipitated. It is a white pulverulent solid which is insoluble in common solvents and coheres to give a fairly clear, very hard film on heating at 120°C. A 1 per cent cobalt nitrate solution with ammonium glycerol phthalate yields a pink, fairly flocculent cobalt derivative which forms a clear, hard film on stoving at 100°C. The salt, moreover, is soluble in a mixture of methylated spirits and benzene and is compatible with nitrocellulose. The green copper compound resembles the cobalt derivative in solubility and in hardness. The calcium salt is formed by adding a 5 per cent solution of calcium chloride in methyl alcohol to

a 20 per cent methanol solution of the potassium salt of a glycerol phthalate resin. The properties of the metallic derivative depend on the resin ingredients. The cobalt compound of a glycerol phthalate condensation product of acid value 126 is virtually insoluble in a toluene-methyl alcohol mixture. The cobalt derivative of the castor oil-modified glycerol phthalate is quite soluble in this solvent. These metallic products may be used in conjunction with fillers and other natural or synthetic resins for the production of molded materials and for impregnating porous bodies.

Alkaline solutions of alkyd resins with an acid number of not less than 100 react with alkyl or aralkyl halides to give resinous products which are compatible with cellulose derivatives. Propyl iodide, for example, may be added to the potassium derivative of a glycerol phthalate resin dissolved in glycol monoethyl ether, and, after heating, the mixture is filtered and evaporated to give a resin which is finally washed with water and dried.<sup>22</sup>

A monoalkyl ester of phthalic acid is readily prepared by heating phthalic acid with an alkylating agent in molecular proportions. The ester is purified by dissolving in sodium carbonate, extracting any dialkyl phthalate with ether and precipitating the monoalkyl ester with acid.<sup>23</sup> By replacing one acidic hydrogen atom of phthalic acid by a metallic atom and the second by an alkyl or aryl radical, compounds are obtained which are soluble in many organic solvents such as ether and acetone. The derivatives furnish a good method of introducing the heavy metals into mixtures as drying agents in paints and varnishes<sup>24</sup> and to reduce the transmission of ultraviolet light.<sup>25</sup> Compounds of the general type

R = alkyl or aryl; M = heavy metal

are readily prepared by mixing an aqueous solution of the sodium salt of the monoalkyl phthalic ester with a solution of a soluble salt of a heavy metal (iron, zinc, manganese, tin, lead, mercury, copper or cobalt). The metal phthalic ester is precipitated in this way. The ferrous and ferric neutral salts of monophthalic esters such as the n-butyl ester are brownish red in color, whereas the zinc, mercurous, mercuric, plumbous and stannous salts are colorless. The manganous and nickel salts are green; the cobaltous and cupric salts are blue. All of the compounds are formed initially as viscous oils, except the copper and manganese salts, which are crystalline at room temperature. These substances simulate those formed directly from solutions of alkyd resins in alkalies.

Metallic derivatives of this type readily form colloids with nitrocellulose. Thus, a nitrocellulose film may be prepared from 10 parts of pyroxylin, 5 parts of zinc n-butyl phthalate and a volatile solvent. The pyroxylin and zinc salt are rendered colloidal in the same way as pyroxylin and camphor would be, the volatile solvent being added to give the required consistency. Films prepared in this manner are uniform and transparent. A non-opaque coating com-

position consists of cellulose nitrate, pearl essence and a salt (iron, copper, cobalt, nickel or manganese) of the half-acid ester of a dibasic acid.<sup>26</sup>

Cobalt butyl phthalate will serve as a drier in varnish inasmuch as it is very soluble in turpentine and oils. An example of a varnish containing this drier consists of tung oil, 50 gals., linseed oil, 12.5 gals., rosin, 120 lbs., turpentine, 125 gals. and cobalt butyl phthalate, 1.22 lbs. Other heavy metal salts of the hemi-alkyl esters may be used in place of the cobalt derivative. Metal alkyl phthalates together with rubber, oils and cellulose derivatives yield a composition which, dissolved in benzene or carbon disulphide, can be used as an adhesive on moisture-proof regenerated cellulose.<sup>27</sup>

By reacting two mols of vegetable oil with one mol of glycerol, the tendency is toward the formation of the diglyceride. The reaction may be expressed as follows:

Reacting the diglyceride with phthalic anhydride, results in the formation of the half-acid ester.

For example 620 g. of linseed oil and 31 g. of glycerol are heated for 30 minutes at 250°C. in the presence of litharge or alkali which serves as a catalyst. The resulting linseed diglyceride is esterified with 148 g. of phthalic anhydride by heating for 30 minutes at 140°C. to yield the phthalic half-acid ester of linseed diglyceride. This product when dissolved in alcohol, neutralized with alkali and treated with a heavy metal salt yields the corresponding derivative. The incorporation of the latter into alkyd resins reduces the transparency to ultraviolet light. The ferric, copper, cobalt, vanadium, cerium and titanium derivatives are effective. The iron compound has a greater retarding value for ultraviolet light than titanium but the iron colors the film. Combination of both metal salts results in the desired opacity and the minimum coloration.<sup>28</sup>

Brown and Bogin<sup>29</sup> have contributed largely to the development of metal alkyl phthalates for use in cellulose acetate compositions. According to these investigators, the addition of varnish gums (dammar, kauri, shellac) to nitro-cellulose lacquers adds body, covering power, adherence and durability without increasing the viscosity. The use of cellulose acetate in lacquers has been limited by incompatibility of many resins and cellulose acetate. Even though the components

<sup>26</sup> G. R. Enslinger, U. S. P. 1,939,676, Dec. 19, 1933, to E. I. du Pont de Nemours & Co.; *Chem. Abs.*, 1934, 28, 1557.

<sup>29</sup> E. K. Brown and C. Bogin, U. S. P. 1,591,653, July 6, 1926, to Commercial Solvents Corp.; *Brit. Chem. Abs.* B, 1926, 753. Canadian P. 290,927, 1926; *Chem. Abs.*, 1926, 20, 2584. German P. 506,957, 1925; *Chem. Abs.*, 1931, 25, 536.

might be dissolved in a liquid without precipitation taking place, the evaporation of the solvent results in the formation of a fogged film. This drawback is not shown by the polyvalent metallic salts of the half esters of phthalic acid. The following equation illustrates the method of forming the compounds:

Phthalic anhydride and butyl alcohol are heated in toluene at 100°C. until the butyl acid phthalate is formed. The solution is neutralized with sodium hydroxide until alkaline to phenolphthalein and then zinc sulphate is added. The resin is freed from solvent and water by distillation below 80°C. Alternatively the alkyl hydrogen phthalate is treated directly with zinc oxide in presence of an organic solvent.<sup>30</sup> The zinc salt of the monobutyl ester of phthalic acid is described as a friable, transparent, gum-like material which is hard enough at room temperature so that it may be pulverized like hard rosin. It softens with increasing temperature to become liquid at 150°C.

Brown and Bogin's<sup>31</sup> method of using these salts to prepare a cellulose acetate-resin lacquer is illustrated by the following example: To 16 oz. of acetone-soluble cellulose acetate dissolved in 2 qts. of a solvent mixture composed of 80 per cent of a low-boiling cellulose acetate solvent (acetone) and 20 per cent of a higher-boiling solvent (diacetone alcohol or tetrachloroethane), 16 oz. of ferric or copper alkyl resin dissolved in 2 qts. of an identical phthalate mixture are added. Frequently it is desirable to add a plasticizer to produce a more elastic or extensible film; dibutyl phthalate may be employed in the solution in amounts up to 100 per cent of the weight of cellulose acetate.<sup>32</sup> The normal monobutyl esters of phthalic acid are said to yield the best resins.

By grinding a pigment in the presence of a liquid ester of phthalic acid (dibutyl phthalate) and a metal salt of the hemi-acid ester of phthalic acid (zinc, copper, iron or aluminum butyl phthalate) a product is formed for use in nitrocellulose enamels. Alternatively, the pigment may be ground in presence of tritoyl phosphate and a metal salt of the hemi-acid ester of phthalic acid.<sup>33</sup> Compounds such as sodium butyl glycerol phthalate, which is formed when part of the free carboxyl group in glycerol phthalate is esterified with a monohydric alcohol and the

remainder of the acid is converted into a salt, together with the corresponding zinc, calcium and copper salts, as well as zinc isoamyl glycerol phthalate, may be used for plasticizing cellulose esters and as components of other synthetic resins.<sup>44</sup> A nitrocellulose coating containing these salts reduces the transmission of ultra-violet light.

Bruson<sup>45</sup> found that polyvalent metal salts of organic acids of the type

"n," whole number greater than unity

"X," hydrogen or alkyl group

"R," an aromatic nucleus

have the property of dissolving in raw linseed, tung, soya-bean and related oils, as well as in turpentine, solvent naphtha, mineral spirits, gasoline and in oil varnishes and paints. Examples of this type of substance are *n*-butylbenzoyl-*o*-benzoic acid, sec-amyl-naphthoyl-*o*-benzoic acid and sec-octyltoluyl-*o*-benzoic acid. Salts of these acids may be incorporated readily in large proportions in such oil compositions as linoleum, printing inks, oil enamels, varnishes and the like and appear to be particularly stable at low temperatures and under varying conditions of dilution and of oil viscosity. They function as siccatives, hardening agents or gloss promoters. When used as siccatives in oil enamels, they do not produce livering or thickening with basic pigments and show little tendency to "after-yellowing" in white enamels.

One example is as follows: to 145 g. of phthalic anhydride in 740 g. of sec-amylbenzene, in a vessel fitted with an agitator, are added 296 g. of anhydrous aluminum chloride in small portions so that the temperature of the reacting mass does not exceed 25°C. The mixture is then stirred continuously for 4 to 5 hours and is next warmed to 45°C. for 5 hours. The dark brown reaction product is decomposed with ice water or with hot soda solution. The latter procedure allows the alumina which forms to be filtered off, that is, after the mixture has been steam distilled to remove unreacted hydrocarbon. The filtrate is then acidified with dilute sulphuric acid and the sec-amylbenzoyl-*o*-benzoic acid separates as a waxy mass which need not be purified for the second step of the preparation.

After washing, the crude waxy acid is carefully neutralized with a 10 per cent sodium hydroxide solution until faintly pink to phenolphthalein and is then treated with a slight excess of a 20 per cent aqueous solution of a water-soluble salt. Cobalt sulphate, manganous chloride, plumbous nitrate, aluminum sulphate or copper sulphate and the like can be used. The metal salts precipitate out as amorphous masses, which are purified by dissolving in an organic solvent (toluene, ethylene dichloride or acetone), filtering and finally evaporating off the solvent. The aluminum, barium, calcium, lead, cerium, magnesium, strontium and zinc salts of sec-amylbenzoyl-*o*-benzoic acid are white, whereas the chromium, cobalt, copper, iron and vanadium salts are colored. The metal salt is usually dissolved in an appropriate solvent before incorporation in the varnish, paint or printing material. Oils or varnishes of the linseed oil type when mixed with the above cobalt, manganese or vanadium salts corresponding to 0.05 per cent metal to the weight of oil show a decrease in the drying time from 24 hours to approximately 6 hours.

A satisfactory amylbenzene for the above reaction is obtained by condensing amyl alcohol with benzene in presence of a dehydration catalyst (concentrated sulphuric acid or zinc chloride). As the length of the chain of the alkyl substituent in the benzene, toluene, xylene or naphthalene nucleus is increased, the oil-solubility of the polyvalent salts increases.

<sup>44</sup> L. C. Swallen and W. J. Bannister, U. S. P. 1,835,915, Dec. 8, 1932, to Commercial Solvents Corp.; *Chem. Abs.*, 1933, 26, 696.

<sup>45</sup> H. A. Bruson, U. S. P. 1,934,033, Nov. 7, 1933, to Resinous Products & Chemical Co., Inc.

Nitrophthalic acid has been substituted for phthalic acid in alkyd resins. The manufacture of 3-nitrophthalic acid in such a way as to avoid losses due to higher nitration products may be carried out as follows:<sup>36</sup> 185 lbs. of phthalic anhydride are agitated with 248 lbs. of concentrated nitric acid (sp. gr. 1.42), to which 322 lbs. of sulphuric acid (sp. gr. 1.84) are slowly added. The mixture is maintained at 95°C. until the reaction is completed, and then cooled to 50-60°C. and run into 500 lbs. of water. After mixing well, the 3-nitrophthalic acid is collected by centrifuging or filtration. Traces of water or nitric acid are removed by agitation with 600 lbs. of benzene and then distilling off the water and nitrobenzene. The remaining benzene is removed either by filtration or by vacuum distillation. The yield is 85-90 per cent based on phthalic anhydride.

The half esters of nitrophthalic acid may be prepared by reacting one mol of an aliphatic or aromatic alcohol with 1 mol of nitrophthalic acid, using a catalyst such as a mineral acid.<sup>37</sup> These half esters resemble phthalic acid in that they will readily form soluble sodium and potassium salts on treating with aqueous alkali. The sodium derivatives give insoluble compounds when mixed with solutions containing salts of heavy metals. The heavy-metal products, although they are insoluble in water, dissolve in many organic solvents. These substances are resin-like in appearance and properties, and may serve as substitutes for natural gums or resins. The zinc, tin and lead compounds are colorless; nickel, chromium and copper are greenish blue whereas iron, cobalt and manganese are reddish derivatives.

#### MISCELLANEOUS COMPOSITIONS AND APPLICATIONS

The reaction of half-esters of dicarboxylic acids with amines yields products such as aniline butyl phthalate, naphthylamine ethyl phthalate or monobutylamine butyl phthalate.<sup>38</sup> The last-named compound is a colorless transparent syrupy liquid, decomposing about 150°C. and soluble in water, methyl or ethyl alcohol, benzene, acetone or ether.

In the production of photographic films, the anti-halation layer can be protected by a thin coating of a non-aqueous solution of a natural or synthetic resin containing at least one hydroxyl or carboxyl group capable of forming a water-soluble alkali salt.<sup>39</sup> An emulsion containing glycerol phthalic acid condensation products, toluene, gelatin, soap and water, with oil or wax if desired, can be used in impregnating paper for producing a waterproof and insulating material. After impregnation, the paper is dipped in an alum or formaldehyde bath.<sup>40</sup> Smooth paper with a high luster and good printing properties is obtained by mixing paper pulp with a small proportion of a metal salt of an acid ester, such as barium monocetyl phthalate. A binder (casein or gelatin) may also be added.<sup>41</sup>

The condensation products from polybasic acids and polyhydric alcohols, either in solution or in the form of an emulsion, may be added to aqueous solutions of water-soluble alkyl cellulose derivatives (as methyl cellulose). The mixture is then subjected, either during or after removal of water, to heat or to exposure to light of short wave length, films or filaments being thus obtained.<sup>42</sup>

## Chapter 47

### Alkyd Resins. Uses in Coatings

It is well known that nitrocellulose solutions give hard quick-drying films. In the development of lacquers employing cellulose esters it was noted that improvements in gloss, adhesion and durability were secured by incorporation of limited amounts of natural resins. Later observations showed that unusual improvements resulted when synthetic resins were employed.

Synthetic resins of the alkyd type have proved themselves preëminently adaptable for use in the preparation of coating materials. As will be seen in the following pages they are frequently utilized as the sole binding agent. They also find very extensive application in conjunction with nitrocellulose. As a preliminary to the discussion of the actual application of alkyd resins for coatings, some consideration must necessarily be given to the general properties and uses of such coatings and to tests which have been made to determine their weathering qualities.

#### GENERAL PROPERTIES OF ALKYD RESIN COATINGS

Synthetic resins<sup>1</sup> of the glycerol phthalate type are now manufactured under several trade names such as "Glyptal,"<sup>2</sup> "Rezyl,"<sup>3</sup> "Teglac,"<sup>4</sup> "Alkydal," and "Dulux";<sup>5</sup> variations in properties being made according to the purpose for which the finished product is to be utilized.

Glyptal lacquers<sup>6</sup> are resistant to all the heavier mineral oils and, after baking, will also resist such substances as gasoline and kerosene.<sup>7</sup> They are unattacked by weak acids and alkalies, and will withstand temperatures of 300°C. They are adaptable to the covering of metallic surfaces (aluminum or galvanized iron) which are normally difficult to coat. A tenacious adhesion is, in fact, one of the outstanding properties of these lacquers, and they produce finishes which are smooth, readily cleaned and, as a rule, resistant to abrasion. These lacquers are applied by spraying, brushing or dipping; they air-dry in 30 minutes, may be handled in 2 hours and will set hard in from 8-10 hours. The drying time is greatly accelerated by heat.<sup>8</sup>

<sup>1</sup> For a review of the use of synthetic resins in lacquers see R. C. Martin, *Metal Cleaning and Finishing*, 1933, 5, 203, 251; *Chem. Abs.*, 1933, 27, 3349, 4425. H. Külln, *Farbe u. Lack*, 1935, 30, 51; *Chem. Abs.*, 1935, 29, 3180. W. Krumbhaar, *Verfkronek*, 1935, 8, 13; *Chem. Abs.*, 1935, 29, 3374. R. Dittmar, *Caoutchouc et gutta-percha*, 1935, 32, 17097, 17131; *Chem. Abs.*, 1935, 29, 3419. E. Fonrobert, *Verfkronek*, 1934, 7, 333; *Chem. Abs.*, 1935, 29, 3180.

<sup>2</sup> The Glyptal resins are a product of the General Electric Co.

<sup>3</sup> The Rezyls and Teglaes are products of the American Cyanamid Co.

<sup>4</sup> Alkydal resins are manufactured by the I. G. Farbenindustrie A.-G.

<sup>5</sup> Dulux was developed by the E. I. du Pont de Nemours & Co. and manufactured also by the Nobel Chemical Finishers, Ltd. (Imperial Chem. Ind., Ltd.).

<sup>6</sup> L. E. Barringer, *General Electric Rev.*, 1929, 32 (12), 660; *Chem. Abs.*, 1930, 24, 1224.

<sup>7</sup> J. McE. Sanderson (*Paint, Oil, Chem. Rev.*, 1932, 95 (11), 38; *Chem. Abs.*, 1933, 27, 3635) has discussed the considerations governing the selection of solvents for alkyd solutions. See also Beck, Koller & Co., *Paint, Oil, Chem. Rev.*, 1934, 96 (10), 18; *Chem. Abs.*, 1934, 28, 4234 for observations concerning the solubility of alkyds with respect to the tolerances of a number of resin solutions for denaturated alcohol, ethyl acetate and mineral spirits, and W. J. Sweeney and J. A. Tilton, (*Ind. Eng. Chem.*, 1934, 26, 693) for hydrogenated naphthas as solvents for alkyd resins. For the use of a hydrogenated petroleum oil (Hydrosolvent) as a solvent for drying oil alkyds, see W. H. Wright, U. S. P. 1,977,000, Oct. 23, 1934, to Schenectady Varnish Co., Inc.; *Chem. Abs.*, 1935, 29, 306.

<sup>8</sup> The kinetics of the baking process of oil varnishes has been studied by R. H. Kieule (*Ind. Eng. Chem.*, 1930, 22, 1370).

Teglacs, although originally developed for use in lacquers, are now finding prominence in both varnishes and enamels. They are essentially phthalic glycerides modified with natural resin acids. Certain of the Teglacs provide a better combination of hardness and toughness than is secured by ester gum. In lacquer enamels they do not impart durability to the extent of the Rezyls, so that they find application chiefly in the sphere of indoor finishes, especially in clear furniture lacquers where hardness and high refractive index impart wearing qualities and high gloss. They are not readily soluble in oils, but dissolve easily in cold toluene, in Cellosolve or in petroleum distillates. They are hard and have a low solvent retention, so that they rub well and are well adapted for use in lacquer sanding sealers.

The Rezyls fall into two classes depending upon whether saturated or unsaturated acids enter into their composition. The saturated Rezyls, also known as the lacquer type of Rezyls, may further be sub-classified as to their compatibility with cellulose acetate or nitrocellulose. The application of the saturated Rezyls in lacquers depends largely on their stability to ultraviolet light and to their retention of gloss and color on exposure to weather. They have, accordingly, been largely used in pigmented lacquers for automobiles, and in architectural brushing lacquers. They have also been used in the production of clear lacquers for bright metal hardware. Because of toughness, color-retention and good solubility, a comparatively low proportion of nitrocellulose is necessary. Rezyls of this type are produced industrially in the form of pale-colored viscous liquids or solid resins softening at 60-69°C., the acid number varying from about 20-35 according to type. They are completely miscible with nitrocellulose and compatible with other lacquer resins, so may be worked in almost any formulation of materials without difficulty. They are soluble in toluene or xylene, or in some cases better, in toluene- (or xylene)-ethyl acetate or butyl acetate mixtures. Dissolved in medium- or high-boiling solvents, they may be used as the vehicle for grinding pigments. Highly basic pigments, such as zinc oxide, are not recommended by the manufacturers for use with these resins.

The unsaturated oxidizing Rezyls are used to some extent in lacquers but find their most extensive application as binders by themselves or in combination with drying oils and resins. They find a wide variety of uses among which can be mentioned drum enamels, freight car paint, house paint, white baking enamel, truck enamels, sign finishes, auto undercoats and printing inks.\* Further treatment of this type of resin as a coating material will be deferred to the following chapter.

There is also a series of high-acid Rezyls for use in aqueous ammonia solutions. The "Ellisols" are a related series of ammonia-water-soluble resins which find application in the impregnation of paper and cloth.<sup>10</sup>

The Alkydal resins<sup>11</sup> are free of natural resin (show no Storch-Morawski reaction) and contain, moreover, no free fatty oils. The absence of phenols enhances their resistance to the action of light. Various grades of quick-drying and baking compounds are produced, which may supplant the usual drying oils or may be admixed with nitrocellulose. The air-drying Alkydals may be somewhat modified by incorporation of small amounts of other natural or synthetic resins, or ester gums; they may be used with any of the usual inorganic pigments, although the use of zinc oxide requires careful formulation on account of the acid number (20-30). The baking Alkydals are designed to dry at 100-

\* J. McE. Sanderson, *Paint, Oil, Chem. Rev.*, 1934, 96 (12), 11; *Plastic Products*, 1934, 10, 141. H. Chase, *Elec. Mfg.*, 1934, 14 (1), 23; *Chem. Abs.*, 1934, 28, 5690.

<sup>10</sup> See Chapter 48.

<sup>11</sup> For tests with Alkydal resins see H. Wolff and B. Rosen, *Farben-Ztg.*, 1933, 36, 1020; *Brit. Chem. Abs. B.*, 1933, 676.

120°C. in one-half to one hour, the addition of about 10 per cent of natural (e.g., dammar) or synthetic resins assists rapid baking and minimizes the tendency to wrinkling found in viscous enamels. Phenolic resins are said to be unsuited for incorporation in this way. Cobalt driers may be added to produce wrinkled and frosted finishes. Alkydals are compatible with nitrocellulose, producing finishes of a high gloss, and particularly free from chalking, which are not, however, suited for sanding and rubbing. The Alkydals may be admixed with drying oils.

Dulux is a drying oil-modified glycerol phthalate resin of extreme hardness and elasticity and permits rigorous treatment of the coated article without flaking or cracking of the film. This will also be treated in a subsequent chapter.

#### DETECTION OF PHTHALATE TYPE RESINS

The density of glycerol phthalate varies from 1.33-1.42, and that of ethylene glycol phthalate from 1.31-1.36; the refractive indices in each case being about 1.56-1.58. Heated in a Pyrex tube over a free flame a phthalate resin will give a white sublimate of phthalic anhydride which can be identified by its reaction with resorcinol to form fluorescein.<sup>12</sup> Scheiber<sup>13</sup> recommends the procedure of heating resorcinol and sulphuric acid with the alkyd resin whereas Cannegieter<sup>14</sup> is in favor of omitting the acid, inasmuch as it leads to charring. A more accurate method<sup>15</sup> involves refluxing the resin in the presence of benzene and alcoholic potash. After distilling off the benzene and alcohol, the unsaponifiable matter is extracted with ether, acidified with hydrochloric acid and further extracted with benzene. The phthalic acid is then precipitated with lead acetate in faintly alkaline solution and the precipitated lead phthalate converted to lead sulphate and weighed.

Apart from qualitative tests, which are reliable methods of detecting phthalates in a coating composition, data relating to specific gravity, refractive index, saponification number, nature of saponifiable matter and melting point may all be applied in the examination of supposed alkyd resins.<sup>16</sup>

#### EXPOSURE TESTS WITH ALKYD RESINS

Gamble and Stutz<sup>17</sup> have studied the light-transmission characteristics of a number of synthetic resins (see Fig. 128). The glycerol phthalate resins were found to be fairly transparent at wave lengths greater than 3000Å.<sup>18</sup> The resins

<sup>12</sup> T. F. Bradley (*Ind. Eng. Chem., Anal. Ed.*, 1931, 3, 308) has worked out qualitative tests for the detection of phthalate resins. The resorcinol test is as follows: "Heat from 0.25 to 1 g. of the resin in a test tube with from 2 to 3 times this amount of pure resorcinol to the boiling point of the resorcinol (205° to 210°C.) for several minutes. Cool and extract with boiling water with agitation of the fused mass. Dilute to from 50 to 100 cc. with distilled water. Render slightly alkaline with dilute aqueous sodium hydroxide solution, when, in the event that phthalates are present, a typical greenish yellow fluorescence of fluorescein will result." The test is also applicable to the sublimate (0.05 g. or more) which may be formed on strong fusion of the resin. It is applicable to the detection of phthalate plasticisers in lacquers.

The phenol test is carried out in the following manner: "A less sensitive but useful confirming test involves the treatment of the resin (or other form of phthalate) with phenol and a condensing agent to form phenolphthalein. Heat 1 gram of the resin with from 2 to 3 times this amount of pure phenol and 10 drops of concentrated sulphuric acid in a test tube over an open flame until visible reaction occurs with formation of an orange or brownish orange melt. Avoid undue charring of the resin by limiting the amount of sulphuric acid and the time and temperature of the operation. After cooling the melt somewhat, extract it with boiling water, with agitation, dilute to 100 cc., and render slightly alkaline with aqueous sodium hydroxide solution. The typical pink of phenolphthalein as exhibited in alkaline solutions is a positive test for phthalates."

<sup>14</sup> D. Cannegieter, *Verfahrenstechnik*, 1934, 7, 256; *Chem. Abs.*, 1935, 29, 3003.

<sup>15</sup> H. Ulrich, *Farbe u. Lack*, 1934, 318; *Brit. Chem. Abs. B*, 1934, 804.

<sup>16</sup> See Chapter 64.

<sup>17</sup> D. L. Gamble and G. F. A. Stutz, *Ind. Eng. Chem.*, 1929, 21, 330.

<sup>18</sup> A filter opaque to rays of wave length greater than 3900 Å is formed from a cellulose derivative

made with glycol, and also the glycerol-phthalic anhydride-oil resins had about the same transparency. Kraus<sup>10</sup> examined the degree of yellowing when various resins and plasticizers were exposed to ultraviolet light separately and in admixture with nitrocellulose. The degree of yellowing was not additive, but was always greater than the sum of the individual yellowing effects, indicating that the effect is due, in part, to reactions among the components of the lacquer. Especially good light-resistance was shown by lacquers containing glycerol phthalate, according to Kraus. Of the synthetic resins, alkyds in conjunction with diamyl phthalate gave the best weather-resistance.<sup>20</sup>

FIG. 128.—Ultraviolet Light Transmission Characteristics of Some Synthetic Resins. (D. L. Gamble and G. F. A. Stutz.)

Experiments conducted by Brendel<sup>21</sup> showed that nitrocellulose lacquers containing alkyd resins remained almost intact after 7 months outdoor exposure. The durability of films containing this type of resin was not a function of the viscosity of the nitrocellulose, a comparatively low proportion of which should be used. The exceptional durability, quick-drying and highly water-resistant surfaces offered by compositions containing nitrocellulose and phthalic anhydride-glycerol resins have led to their adoption under exacting conditions such as those which arise in aircraft manufacture.<sup>22</sup>

Gardner<sup>23</sup> has carried out tests with varnishes containing alkyd resins exposed to salt-water air. A lacquer containing equal parts by weight of nitrocellulose and glycerol phthalate-plasticized resin failed in 9 days after application of one flow coat. The steel under the film showed very slight rust. This lacquer was better than a combination phenolic-phthalic anhydride glycerol ester-tung oil varnish tested under the same conditions. The protection afforded against the

containing sodium benzoate, phthalic anhydride and potassium acid phthalate, according to R. B. Withrow, U. S. P. 1,933,734, Dec. 12, 1933, to General Development Lab., Inc.; *Brit. Chem. Abs. B*, 1934, 909.

rusting of steel, for sub-sea-water service, was tested by exposure at 45° inclination during the day and immersion in 3 per cent sodium chloride during the night for six months. Addition of alkyd resin to linseed oil paints and reduction of pigment concentration was without advantage save in the case of the basic lead chromate paints.<sup>24</sup> Other tests on spar, semi-spar and rubbing lacquers again emphasize the superior weathering properties of compositions containing alkyd resins (see Fig. 129). A number of Rezyls were employed in these tests.<sup>25</sup>

Van Heuckeroth<sup>26</sup> has examined the effect of various plasticizers used in a series of lacquers submitted to exposure. A lacquer containing Rezyl<sup>27</sup> gave the best results on red cedar and (in other exposure tests) on metals previously coated with various primers. Alkyd-type primers were found to be superior

Courtesy American Cyanamid & Chemical Corporation

FIG. 129.—Comparative Durability of a Rezyl Lacquer (left) and an Oleo-Resinous Spar Varnish Exposed under Identical Conditions.

to the oleo-resinous variety. Bolme<sup>28</sup> also carried out exposure tests on nitrocellulose lacquers and alkyds, using various accelerated weathering devices. Gettens<sup>29</sup> found that alkyd resins have a low moisture-permeability and, on this basis, are useful in coating materials for the protection of works of art. The durability of a lacquer coating is found to increase with the Rezyl content, which is not the case with other resins. For exterior clear finishing lacquers of great durability on both wood and metal surfaces, three to four parts of Rezyl to one part by weight of nitrocellulose gave good results. For automobile and furniture lacquers more nitrocellulose should be incorporated. Kolke,<sup>30</sup> in a study of the weathering tests of nitrocellulose lacquers on wood, emphasizes the fact that by using appropriate ground coats alkyd resins improve the coating. As shown by exposure tests, pigments have a definite effect on the durability of the paints prepared from drying-oil alkyds and bodied linseed oil.<sup>31</sup> A glaze for walls and tiles said to be resistant to weather and acids is produced by applying in the

cold a mixture of quartz, Sorel cement, magnesium sulphate and nitrocellulose, then applying a further coat of nitrocellulose and glycerol phthalate resin and a final hardening lacquer containing acetyl cellulose.<sup>23</sup>

#### ALKYD RESIN COATINGS ON METALS

The alkyd resins find one of their most promising fields of application in the coating and protection of metal surfaces.<sup>23a</sup> One method of utilizing the resin is as an ingredient of a paint consisting of finely divided aluminum suspended in a volatile solvent in which the resin (from an equimolecular mixture of glycerol and phthalic anhydride) has been dissolved. The metal (iron, steel or copper) is coated with this paint, the solvent is allowed to evaporate, and the metal is heated to 380°C. to volatilize the resin. Final heating is carried out at a still higher temperature to cause the aluminum to diffuse into the surface layers of the metal.<sup>23</sup> Metal powders other than aluminum may be used; zinc, copper alloys, silver and gold powders have been suspended in a solvent consisting of butyl alcohol, toluene and naphtha with an alkyd resin modified with drying oils and drying oil acids together with a small percentage of rosin. Paints containing zinc or aluminum may be applied directly to iron or copper and the zinc and aluminum alloyed by heating.<sup>24</sup>

The chief difficulty which arises in connection with the use of cellulose lacquers on metal surfaces is the fact that such lacquers have a tendency to crack away from the surface to which they have been applied.<sup>25</sup> The disadvantage has been successfully overcome by providing the metal surface with an underlying or priming coating of a resin of the glycerol and phthalic anhydride type.<sup>26</sup> In some cases plasticizing agents (indene, glycol diacetate, diethyl phthalate, anisole, triacetin or tricresyl phosphate) may be introduced with advantage into the resin during its manufacture. A solution of the glycerol phthalate resin in a solvent consisting of 30 parts of acetone, 30 parts of benzene, 30 parts of alcohol and 10 parts of ethyl lactate by volume may be used. Such a solution of 0.925 specific gravity at 60°F. is suitable for spraying. A film produced by spraying is first air-dried and subsequently baked for 20-40 minutes at 125-175°C. Under these conditions, the resin is transformed into the B-stage. The adjustment of time, temperature and other baking conditions must be such as to expel all of the solvent from the lacquer and render the coating non-tacky, but still soft enough to provide the proper anchorage for the cellulose lacquers to be superimposed. When a high-boiling solvent is present some of it will be retained in the baked resin, thereby increasing its flexibility. A cellulose lacquer in a solvent consisting of butyl phthalate, dibutyl phthalate, ethyl lactate, ethyl acetate, glycol diacetate or similar volatilizable material is then applied by spraying. The solvent of the cellulose lacquers softens the underlying resin somewhat and thereby binds the two films together. The time required for baking the resin coating, and also

<sup>26</sup> P. W. Ham (*Official Digest, Fed. Paint Varnish Prod. Clubs*, 1934, 135, 102; *Chem. Abs.*, 1934, 28, 3002) in a study of the problem of "lifting" on recoating, found that only heat-convertible oils and resins lift and the tendency reaches a maximum in a few days and then disappears. A lacquer thinner will dissolve the film before this maximum is reached but not after. A film which remains soluble may be recoated by spraying and will not lift.

the baking temperature, may be reduced by converting the A-stage alkyd resin to the C-stage in mass, before it is applied to the surface to be coated. The otherwise insoluble resin in this case is dispersed in a solvent by heating the resin in contact with the solvent in a closed vessel. Glyptal resin, for example, may be dispersed in acetone by heating at 150-170°C. in an autoclave for 36 hours.

A Glyptal baking lacquer (839-P) may be used with or without pigments on glass, glazed or unglazed porcelain, aluminum, copper, brass and a great many other metals.<sup>37</sup> It may be applied by brushing, dipping or spraying, to yield a flexible, insoluble, adherent and color-permanent coating. For spraying it should be thinned about 50 per cent with equal parts of alcohol and benzene. The pigments which may be employed are given in Table 47; when no pigment is used, a dark-yellow coating is obtained. Temperature and time are given in Table 48.

TABLE 47.—*Pigments for Use in Glyptal Enamels.*

Temperature in °F.	Time in Hours
260	10
300	4 5
350 ..	2
400...	1
450.....	25/60

According to Van Heuckeroth's<sup>38</sup> exposure tests, alkyd resins are superior to an oleoresinous product as metal primers under lacquers.<sup>39</sup> In finishing processes, it has been found that a lacquer has a rough surface due to uneven flowing, uneven surface shrinkage and due also to accumulation of spray dust and dust from the air. Smoothing of the coat can be accomplished by sanding and mist spraying. The latter procedure can be avoided by coating the articles with an alkyd resin, rubbing down with an abrasive material and then heating to 70-120°C. to eliminate the abrasion marks and to produce a smooth lustrous finish.<sup>40</sup> A method of treating aluminum vessels, developed by Brossman,<sup>41</sup> consists in scouring the vessel, filling it with an alkyd resin, heating to 90-110°C. for from 10-24 hours under a pressure of 90 lbs. per square inch, draining and baking at the same temperature for 10-12 hours to harden the resin in the pores. In finishes for zinc and aluminum die-cast parts, particular care in cleaning is necessary due to the variable porous nature of the castings. Baked-on alkyd enamels are preferred for finishing operations.<sup>42</sup> Another coating material for metal surfaces consists of a mixture of a synthetic resin which is capable of being hardened (phenol-

<sup>37</sup> General Electric Co., *Special Products Section Circ.* GEA, 1927, (Sept.), 840.

<sup>38</sup> A. W. Van Heuckeroth, *Circ., Am. Paint, Varnish Mfrs. Assoc.*, 1931, 399, 377; *Chem. Abs.*, 1932, 26, 608.

<sup>39</sup> The use of clear top varnishes on lithographed metal advertising signs in order to obviate the chalking and fading of certain colors is recommended by H. A. Gardner (*Amer. Paint, Varnish Mfrs. Assoc.*, 1933, 427, 230; *Brit. Chem. Abs.* B, 1933, 1068). Promising tests were shown by nitrocellulose and Rezoglas (polystyrene) plasticized with 25 and 50 per cent, respectively, of diphenyl phthalate, nitrocellulose lacquers with a high resin content of Rezyl No. 19 and Rezyl Balsam No. 33, and a "44-gal." modified phenol-formaldehyde-tung oil varnish. A baking oil primer is needed.

<sup>40</sup> F. M. Crytler, U. S. P. 1,904,417, April 18, 1933, to Jones-Dabney Co.; *Brit. Chem. Abs.* B, 1933, 1032.

<sup>42</sup> H. Chase, *Synthetic and Applied Finishes*, 1934, 5, 208; *Brit. Chem. Abs.* B, 1935, 32.

formaldehyde or alkyd resin) with silicon or an acid-proof metal silicide. This is applied to metal tanks, enamelled apparatus and ceramic ware as a coating or lining, and subsequently hardened. Alternatively the resin may be applied and the silicon then incorporated before the hardening process.<sup>48</sup> A gold leaf decalcomania type of decoration can be applied to a surface of lacquered steel by means of an adhesive which includes an alkyd resin, with an overlying coating consisting of an oil-modified resin of the same general type.<sup>49</sup>

Another application of the alkyd resins is in the coating of tin cans to prevent the discoloration of crab meat. Due to the sulphide content of crab meat, it is necessary to keep metals from immediate contact. A lacquer consisting of 20 per cent of an alkyd resin, 40 per cent combined linseed and tung oil and 40 per cent petroleum thinner containing drier is sprayed on to the tin plates and baked at 250-375°F. The resulting coat is a non-conductor of electricity, impervious to moisture and contains no ingredients which will form sulphides.<sup>49</sup>

#### USE OF ALKYD RESINS IN PRINTING

Alkyd resins have found a number of applications in connection with the manufacture of inks for plain or relief printing.<sup>48</sup> Thus Fleischmann and Jordan<sup>48</sup> have prepared intaglio printing colors from a finely dispersed coloring material and a solution in a volatile organic solvent of an alkyd resin. The following examples illustrate the compositions used:<sup>48</sup> (1) The condensation product of glycerol, linseed oil, phthalic anhydride and rosin is dissolved in toluene, with Lithol Fast Scarlet R ground in; a drier being added if necessary. (2) Chrome yellow is added to a solution in benzyl acetate of the condensation product of ethylene glycol monolinoleic ester, glycerol and phthalic anhydride, with which lead-manganese resinate is subsequently incorporated. (3) Nitrocellulose, a rosin-modified glycerol phthalate and dibutyl phthalate are dissolved in ethylene glycol monoacetate and cyclohexanol and the resulting solution is ground with zinc green.

Scheiber<sup>49</sup> has employed for the preparation of printing ink a vehicle containing the ester of a polyhydric alcohol with 9,11-octadecadiene-1-carboxylic acid which is prepared by the vacuum distillation of castor oil acids. The esters may be boiled to an appropriate consistency before use. Davis,<sup>50</sup> in forming a type-impressible stencil sheet, used a glycerol phthalate resin made up from 200 parts of phthalic anhydride and 100 parts of glycerol. The reactants were heated for an hour at 185°C., whereupon the temperature was raised slowly to 210°C. and kept at this point until a sample on cooling gave a clear, brittle, yellow-colored resin without appreciable tack and with no stickiness. To 225 cc. of a 10 per cent solution of this resin in acetone were added 45 cc. of castor oil, 30 g. of chlorinated naphthalene, 15 g. of Japan wax and 15 cc. of paraldehyde. A small amount of nitrocellulose may also be added and the material is then coated onto a support such as yoshino paper and dried. The mixture forms a homogeneous semi-fluid mass at ordinary temperature.

## MANUFACTURE OF LAMINATED GLASS

The condensation products from glycerol or glycol and phthalic acid have found application in the manufacture of laminated glass. The good adhesive properties of the alkyd resins, coupled with the fact that they do not darken appreciably on prolonged exposure to light, render them useful in this connection. Zola<sup>51</sup> employed as a basic resin for this purpose the product of condensation of glycerol with adipic or sebacic acid. Such a resin alone has a tendency to show sheeting lines in the laminated product, and to avoid this difficulty other resins are added, among which are other alkyd resins, phenol-formaldehyde resins, toluenesulphonamide derivatives and ester gum. The basic resin is ordinarily compounded with 60 per cent of toluene. The basic with the added resin is then dissolved in a solvent consisting of 45 per cent of heavy naphtha, 45 per cent of toluene and 10 per cent of ethyl acetate. In compositing the sheets of glass and cellulose ester plastic, the resin solution is sprayed in a thin film, which is allowed to dry in the atmosphere. The sheets are then placed together and the sandwich is exposed to heat and pressure. In a later development Zola<sup>52</sup> has used fatty acids or oils (castor, linseed, maize, tung and soya bean oil) as modifiers for the glycerol-phthalic anhydride resin.

Field and Haslett<sup>53</sup> have also employed alkyd resins either alone or mixed with other synthetic resins (phenol-formaldehyde or phenol-urea-formaldehyde) for manufacturing non-splintering glass. The mixed resins may be applied alone or with other materials such as Canada balsam, euphorbium resin or cellulose ester solutions. Sprenger<sup>54</sup> made a similar application of condensation products of the glycerol-phthalic anhydride type.

Laminations of glass, wood, textile materials or cellulose acetate sheets may be assembled in a bath containing an alkyd resin in the A-stage of condensation.<sup>55</sup> The resin is used in a solvent consisting of ethyl and butyl lactates and dichloroethylene. After removal from the bath the composite material is consolidated by compression at 300 lb. per square inch at 90-130°C.

Another method of manufacture of non-splintering glass is to utilize for cementing purposes one or more polybasic acid-polyhydric alcohol condensation products in a warm liquid or viscous condition. Cellulose derivatives or polyvinyl esters may also be incorporated.<sup>56</sup> The resin may also be applied in solution to the glass, dried and polymerized and the glass sheets then pressed on to the sheet of cellulose material.<sup>57</sup>

## APPLICATIONS OF ALKYD RESINS IN COATING COMPOSITIONS

Kienle and Adams<sup>58</sup> treat a solution of resin prepared from glycerol and phthalic anhydride containing excess acid, with an alkali to neutrality. The clear solution, decanted from the insoluble salts, can be mixed with basic

pigments to form enamels. Litharge may be used as an ingredient in the preparation of a composition which consists of a drying oil acid-modified glycerol phthalate. The components are heated at 170-225°C. for 2.5-6 hours during which time 1-10 per cent of litharge, based on the weight of resin, is slowly added with agitation. The resin is cut in a solvent to remove excess litharge and any insoluble lead compounds. This treatment is found to impart improved water-resistance, increased rate of set-up and increased hardness.<sup>60</sup> The coatings formed are free from after-tack.<sup>60</sup> Alkyd resins incorporated with an inorganic softening agent (graphite, asbestos powder or talc) and a filler (red lead or litharge) are said to yield a resistant, acid-proof coating.<sup>61</sup> In this instance, for coatings consisting of multiple layers the hardening agent may be added to the final layer, the softeners being confined to the lower layers.

Barringer<sup>62</sup> has described an alkyd resin coating applied to an asbestos composition backing. A sheet composed of asbestos and portland cement is used as the foundation, this being given one or more coats of a solution of glycerol phthalate resin followed by baking the article for ten or twelve hours at 150-200°C. to convert the resin to a hard insoluble form. An alternative method of applying the coating is by sifting the powdered resin upon the surface while the article is at a temperature of about 200°C. The first coat is usually clear and acts as a primer. Indene, dibutyl phthalate or tricresyl phosphate can be used as plasticizers. These coatings have good heat-resistance and are very adherent, durable, odorless, impervious to liquids and are useful for refrigerator linings. Another method of applying these resinous substances to surfaces such as wood, metal, paper, porcelain or asbestos is to pass a stream of the finely powdered resin through a flame or other heating zone on to the surface, and then to bake the coated article.<sup>63</sup>

Wright<sup>64</sup> has described a composition for coating by spraying or dipping, formed from an alkyd resin in the B-stage with a pigment suspended in a volatile liquid (carbon tetrachloride, turpentine or paraffin hydrocarbons) in which liquid the resin does not tend to soften. The coated articles are baked from 2-12 hours at 125-180°C. The alkyd resin alone may also be dissolved directly in a mixture of solvents of graded boiling points (acetone, denatured alcohol, benzene and ethyl lactate) and the coatings formed from such a solution are first baked at 100° and subsequently at 200°C.<sup>65</sup>

Jaeger<sup>66</sup> has used the glycerol phthalate resins as an outer coating on candles to prevent drip while burning and to insure greater freedom from breakage. The coating may be applied by dipping or brushing and consists of alkyds or alkyds

<sup>60</sup> R. T. Ubben (U. S. P. 1,998,744, Apr. 23, 1935, to E. I. du Pont de Nemours & Co.) reported that water-resistant films are obtained if a polyhydric alcohol (approximately equivalent to that required to neutralize the excess acid) is added to an aqueous solution of alkyd resin containing a volatile base (ammonia or methylvamine), and baking the films resulting from such a composition.

modified with phthalide,<sup>67</sup> phenol-aldehyde, phenol-furfural, nitrocellulose or natural resins.

A glycerol phthalate type resin has been utilized in the making of an artificial silk. The heated resin is extended into air at a temperature of 150-200°C. Also an acetone solution of alkyd resin may be passed into a coagulating bath and the filaments subsequently baked.<sup>68</sup>

Cellophane or a similar smooth-surfaced base can be coated with a solution of an alkyd resin and a plasticizing agent; the resulting coating is found to adhere firmly, while the surface is glossy and resistant to moisture and heat. On a viscose base, the resulting sheet has fair dielectric strength.<sup>69</sup>

### COATINGS ON RUBBER

Uncured rubber cloth or other products may be coated with a lacquer containing an alkyd resin made in the presence of a hydroxylated fatty oil and a urea-formaldehyde condensation product. The coating is hardened and the rubber is simultaneously vulcanized by treatment with a solution of sulphur chloride in carbon disulphide or naphtha.<sup>70</sup> It has been found that the limpness of latex-treated fabrics is obviated by previously mixing the aqueous rubber dispersion with an aqueous solution of an alkyd resin.<sup>71</sup> It is probably significant in this connection that a suspension of an alkyd resin in a mineral oil is stabilized by a few drops of a rubber solution.<sup>72</sup> In preparing artificial leather, a coat of rubber is applied to fabric, embossed and then coated with pigmented varnish containing oil and asphalt and finally baked to vulcanize the rubber and dry the varnish; the material may be subsequently "souped" with a composition consisting of pyroxylin and a pigmented alkyd resin.<sup>73</sup> Moreover the rubber may be coated directly with a castor oil-modified alkyd resin.<sup>74</sup> A lacquer formed from an alkyd resin, with drying oils or their acids to increase the elasticity, has been employed as a coating for wire before the application of a vulcanized rubber layer.<sup>75</sup> Heat-vulcanized rubber has been coated with a glycerol phthalate resin diluted with glycerol and glycol together with gelatin.<sup>76</sup>

Rubber can be attached to a rigid surface such as metal, porcelain, glass or wood by interposing the rubber with a glycerol phthalate resin and finally hardening with heat.<sup>77</sup> Certain alkyd resins will also plasticize chlorinated rubber.<sup>78</sup>

## USES OF ALKYD RESIN COATINGS WITH CELLULOSE ESTERS

The use of alkyd resins in conjunction with nitrocellulose or cellulose acetate in lacquers is one of the most important developments in this field in recent years.<sup>79</sup> Bradley<sup>80</sup> has shown that the Rezyls act as preservatives for nitrocellulose. Resins as a rule decrease the durability of the nitrocellulose film, but with the Rezyls the converse is true. As much as 4-5 parts of Rezyl may be mixed with 1 part of nitrocellulose, the durability of the resulting film being greater, within certain limits, the larger the amount of the added synthetic resin. With respect to mechanical properties, tensile strength, distensibility and durability, the alkyd resin functions primarily as a resin, nevertheless it acts to some degree as a plasticizer. The optimum percentage of alkyds for best results with nitrocellulose is probably very high.<sup>81</sup>

The compatibility of the Rezyls with nitrocellulose in a wide range of solvents has been examined by Hofmann.<sup>82</sup> Resins and solvents can be divided into two groups, the alcohol-soluble type and the hydrocarbon-soluble type. The alcohol-type resins are most easily soluble in the alcohol-type solvents and the hydrocarbon-type resin in the hydrocarbon-type solvents. In some "alcoholic" solvents (mesityl oxide, ethyl lactate or butyl Cellosolve) clear solutions and films were obtained, whereas in a number of solvents (sec-butyl acetate or amyl acetate) the addition of alcohol or toluene was needed to ensure satisfactory results. In general, compatibility is most readily obtained by using solvents and resins of corresponding types, that is, an alcohol-type solvent and an alcohol-soluble resin.

A cracked petroleum distillate (b.p. 130-150°C.), consisting essentially of monolefins, when added to monochlorobenzene was found by Lougovoy<sup>83</sup> to be a good diluent for nitrocellulose lacquers. Natural resins (rosin ester) and castor oil-modified glycerol phthalate resin as well as glycerol phthalate benzoate can be used along with nitrocellulose. Sec-butyl alcohol diluted with toluene produces a marked lowering of viscosity of the nitrocellulose coating composition without affecting toughness and durability. Isopropyl alcohol likewise has this property.<sup>84</sup> Diacetone alcohol, when mixed with unsaturated petroleum hydrocarbons of limited boiling range, acts as a nitrocellulose solvent. The addition of a higher alcohol is necessary to blend the diacetone alcohol and the hydrocarbons. Cottonseed oil fatty acid-modified glycerol phthalate can be added to this composition.<sup>85</sup>

Hofmann and Reid<sup>86</sup> determined that the resins from phthalic anhydride and ethylene glycol are compatible with cellulose acetate. They function in the combined role of resin and plasticizer. A lacquer containing 9 parts cellulose acetate, 7 parts glycol phthalate and 50 parts pigment when sprayed onto panels coated with an oleoresinous primer and surfacer gave films of good flexibility but of rather unsatisfactory adhesion. Using a pyroxylin primer and surfacer the results were

<sup>79</sup> Very few of the natural or synthetic resins are compatible with cellulose acetate. The "Santolites" (toluene sulphonamide) (see Chapter 34), some Rezyl balsams and some "Plasto" resins (see Chapter 11) give fairly satisfactory films with cellulose acetate, particularly when plasticized with ethyl phthalyl ethyl glycolate, methyl phthalyl ethyl glycolate and dibutyl phthalate. more satisfactory. The strong influence of constituents on the properties of the film has been emphasized by Herzog, Hildesheimer and Medicus,<sup>87</sup> these investigators having examined the influence of a variety of organic compounds on nitrocellulose lacquers.

Lamb and Gilman<sup>88</sup> have explored the possibilities of using Rezyls with cellulose for leather dressings. Up to 3 parts of the resins for 1 part of nitrocellulose were used together with a solvent mixture consisting of ethyl acetate and ethyl lactate with a small quantity of butyl alcohol and up to 70 per cent of toluene as a diluent. The results were not satisfactory for glove leather, as an insufficient elasticity resulted. The following formula gave good results for Morocco leather: 40 parts of ethyl acetate, 80 parts of ethyl lactate, 40 parts of butanol, 240 parts of toluene, 16 parts of nitrocellulose (film), 48 parts of resin and 16 parts of ultramarine blue. A disadvantage common to most finishes with a cellulose ester base is that, if sufficient pigment is added to give a good covering, the finish loses all its brilliance and tends to become brittle. Apart from this disadvantage, the glycerol phthalate resin imparts softness, flexibility and resistance to deterioration by ultraviolet light. Nitrocellulose varnishes which remain elastic and which are resistant to changing temperature conditions and useful for covering natural and artificial leather are prepared by introducing zinc naphthenates into nitrocellulose, together with alkyd resins.<sup>89</sup>

#### ALKYD RESINS IN LACQUER COATINGS AND AS PRIMER COATINGS

Work carried out in the author's laboratory has resulted in a number of direct applications of glycerol-phthalic anhydride resins with cellulose esters. Thus a primer coating of an alkyd resin on wood or metal was found to be satisfactory with a superimposed coating of a nitrocellulose composition.<sup>90</sup> Wood lacquers for furniture coating should possess great hardness and toughness and enough elasticity to withstand contraction and expansion. A low-viscosity nitrocellulose is used which may be prepared by boiling motion-picture film in water rendered slightly alkaline and heating the emulsion-free material to 160°C. for 2-5 seconds. A castor oil-phthalic-glyceride is prepared by heating 47 parts of glycerol, 80 parts of phthalic anhydride and 40 parts of castor oil under reflux. To make up a gloss-white enamel, 12 parts of low viscosity nitrocellulose, 6 parts of castor oil-phthalic-glyceride, 5 parts of zinc oxide, 5 parts of titanox, 5 parts of dibutyl phthalate, 10 parts of butyl propionate, 10 parts of butyl acetate, 5 parts of butyl alcohol, 10 parts of ethyl acetate and 30 parts of toluene are used.<sup>91</sup> Weber<sup>92</sup> prepared a cellulose ester composition for films and molded articles by incorporating with cellulose nitrate the reaction product of a vegetable oil (corn, tung or blown rapeseed oil) and an organic acid obtained from either castor or soya bean oil together with a polyhydric alcohol and phthalic anhydride. Nitrocellulose, when admixed with a rosin-glycerol phthalate resin which is soluble in nitrocellulose solvents, gives rise to a coating composition.<sup>93</sup>

Precipitation of the nitrocellulose during evaporation of volatile solvents (acetone, ethyl acetate) and consequent "blushing" of the film can be prevented

by incorporating glycerol-fatty acid resins<sup>94</sup> or by means of balsams of analogous types. Such a balsam can be prepared from 106 parts of diethylene glycol, 100 parts of coconut oil and 148 parts of phthalic anhydride.<sup>95</sup>

A sulpho-chlorinated fatty acid-modified glycerol phthalate resin produced from phthalic anhydride, glycerol, cottonseed fatty acids and sulphur monochloride is adaptable for use with nitrocellulose in coating compositions.<sup>96</sup> A quick-drying coating material is obtained by mixing nitrocellulose of medium viscosity (e.g., "4-10 sec.") with an alkyd resin which is soluble in benzene anhydrous methyl alcohol mixtures.<sup>97</sup> A glycerol benzoate-salicylate-abietate resin may be rendered light in color by cooling the reaction product under reduced pressure or in an inert gas such as nitrogen.<sup>98</sup>

The incorporation of castor oil with the glycerol-phthalic anhydride resin for admixture with nitrocellulose affords a further method of modifying the resulting coating material.<sup>99</sup> The use of castor oil renders the product soluble in ethyl and butyl acetates or mixtures of these with the corresponding alcohols. A resin prepared from 74 parts of phthalic anhydride, 45 parts of glycerol and 33 parts of castor oil at 290°C. is hard; the incorporation of a larger proportion of castor oil yields a softer product. Increased quantities of the softer type of composition, admixed with nitrocellulose, renders possible the production of more flexible and longer-wearing artificial leathers. Added to this, the elimination of castor oil odors and that of rancidifying oils is of special value in the manufacture of artificial leather.

#### COATINGS ON PAPER

Alkyd resins in conjunction with nitrocellulose have been applied to the production of a grease-resistant paper. A development by Bradley<sup>100</sup> utilizes a composition such as the following: 40 parts (by weight) of low-viscosity nitrocellulose, 40 parts of cottonseed-phthalic glyceride resin, 20 parts of dibutyl phthalate, 135 parts of ethyl acetate, 135 parts of benzene and 5 parts of paraffin wax. The paper is ordinarily run over rolls or through a bath of the material. The wax in the solution substantially checks the evaporation of the solvents at room temperature; this is important in that it largely eliminates the possible toxic hazard of benzene vapors. The paper is dried at 140°F. In order to secure proper impregnation of the paper it is best to submit the coated material to the action of hot calender rolls. A coating of greatly reduced inflammability is secured by a high resin content, by the use of tricresyl phosphate as a plasticizer and by the employment of hydrated inorganic bodies as fillers.

A further application of modified alkyd resins is in the production of grease-resisting box board and grease-proof paper. Paper or board, which has been made from ground wood and sulphite pulp, or similar fibrous material, is used and is impregnated with wax which has been added in the form of an emulsion in the beater. A typical composition is the following: 20 parts of nitrocellulose solution, containing 20 per cent of low viscosity nitrocellulose in acetone, are mixed with 8 parts of a resin solution (cottonseed-phthalic-glyceride resin dissolved in an equal volume of acetone). One part of dibutyl phthalate is added. The solution, which is of low viscosity, may

be applied to paper by brushing or coating. Paper of this type is used in making boxes, cartons, ice cream containers and the like.<sup>101</sup>

Paper with a high  $\alpha$ -cellulose content can be impregnated with an alkyd resin to form a translucent heat-resistant paper useful for shades of lamps. The paper is made from spruce chips digested with sulphurous acid, blown and washed. About 5 per cent of the  $\beta$ - and  $\gamma$ -cellulose are left in the paper to act as a binding agent.<sup>102</sup>

A stratified film for decorative purposes described by the author<sup>103</sup> has a stratum, such as a pigmented nitrocellulose mixture, with an overlying protective stratum of nitrocellulose and a compatible resin of the oil-glyceride type. The top layer is free from pigment and is transparent. A waterproof brilliant surface is obtained on paper, cloth or skins by coating with nitrocellulose, a plasticizing agent consisting of a blown oil and finally covering with an alkyd resin varnish.<sup>104</sup>

#### OTHER CELLULOSE ESTER-ALKYD COATING COMPOSITIONS

A considerable number of resins of the glycerol-phthalic anhydride type, but varying in their exact constituents, have been suggested for use with nitrocellulose in coating and filling compositions. The alkyd resin may be derived from a polybasic acid (phthalic, halogenated phthalic acid or aliphatic dibasic acids<sup>105</sup>) and a polyhydroxy alcohol (glycerol, the hydroxyalkyl ethers of glycerol,<sup>106</sup> the hydroxyalkyl ethers of glycol,<sup>107</sup> pentaerythritol or sorbitol<sup>108</sup>). In place of nitrocellulose, the lower fatty acid esters of cellulose can be employed. Cellulose triacetate or butyrate or acetone-soluble cellulose acetate<sup>109</sup> can be incorporated with condensation products of phthalic<sup>110</sup> or aliphatic acids with ethylene, butylene glycol<sup>111</sup> or pentaglycerol.<sup>112</sup> In one example, nitrocellulose, a condensation product of succinic acid and glycerol, and tricresyl phosphate are dissolved in ethylene glycol monoethyl ether, ethyl alcohol and methyl acetate. Moreover ethyl cellulose can be blended with glycerol linoleate-ricinoleate-phthalate, or benzyl cellulose and mixed with glycerol abietate-palmitate-maleate.<sup>113</sup>

The adhesion of cellulose lacquers to smooth surfaces is improved by incorporation of about 5 per cent of alkyd resin previously plasticized with oleic acid. A primer containing an alkyd resin plasticized with materials such as oleic acid or tricresyl phosphate, and cured by heat treatment *in situ*, is also found to improve the flexibility of insulating varnishes.<sup>114</sup> One or two coats of the primer are applied and stoved for 1 minute at about 310°C., subsequent coatings of oil varnish being stoved for 1 minute at 350°C. Resins prepared from non-resinous organic acids have a notable resistance to water. Increase in the amount of

monobasic acid used results in a lowering of the softening or melting point of the composite resin and renders it more readily soluble.<sup>115</sup>

Free acids have been found to have a plasticizing action on nitrocellulose films. Besides the higher fatty acids, phthalic and benzoic acids exercise definite softening action in thin nitrocellulose films. The presence of an ordinary type of plasticizer (tricresyl phosphate, dibutyl phthalate) seems to be necessary to prevent the acid from crystallizing. When the ordinary plasticizer is omitted, the acid crystallizes during the evaporation of the solvent and this often leads to the formation of novel and artistic finishes. When this does happen, the plasticizing action of the acid is lost.<sup>116</sup>

Nebel<sup>117</sup> has described a sanding sealer consisting of a cellulose derivative, a sanding promoter (calcium or zinc stearate) and a resin formed from glycerol, phthalic anhydride, rosin and stearic acid. An oil-modified alkyd resin, together with a plasticizer if required, may be used for coating sheets of regenerated cellulose. The coating is dried subsequently, at a raised temperature, and is non-tacky, moisture-proof and flexible.<sup>118</sup> Kramer<sup>119</sup> utilized phenoxyethyl phthalate, methylphenoxyethyl phthalate or methylphenoxyethyl laurate as softeners for lacquer compositions containing cellulose acetate.

A mixture of cellulose acetate or similar ester of cellulose with a relatively large amount of plasticizer and of alkyl phthalate or tartrate, or of a glycerol ester, has been found to yield a good insulating material.<sup>119a</sup> A duplex waterproof foil containing an alkyd resin as one of its constituents is made by the following method. A layer containing nitrocellulose waterproofed by inclusion of a wax (Japan wax), a fat (lanolin) or paraffin wax, together with an oil-soluble alkyd resin is superimposed by casting on a cellulose acetate film.<sup>120</sup>

Cellulose esters can be colored before esterification. Cotton linters are first dyed by means of a vat dye, the dyed cellulose esterified with an organic acid (acetic or formic) and the product used with an admixture of glycerol phthalate resin modified with phthalide, in which some of the same dye has been dissolved.<sup>121</sup>

A non-blushing nitrocellulose lacquer, described by Rogers<sup>122</sup> contains a cumarone-indene resin<sup>123</sup> melting above 110°C. and an alkyd resin. The total resin is not more than 18 per cent by weight of the lacquer, while the cumarone-indene constituent makes up approximately 25 to 40 per cent of the total resin.

The proportion of alkyd resin which may be added to a cellulose varnish and form a clear solution is said to be increased by the addition of so-called homogenizing agents.<sup>124</sup> Compounds such as nitrobenzene, benzaldehyde and pyridine have this property. For example, a mixture of 1.5 kg. of a 21 per cent solution of nitrocellulose and 1.0 kg. of a 50 per cent solution of phthalic acid-glycerol resin is cloudy, but on addition of 1 kg. of nitrobenzene to the mixture the turbidity disappears and hard, clear films result when the solution is employed as a varnish.

The quantity of the homogenizing agent needed depends on the solvent and also on the degree of condensation of the alkyd resin. The amount of nitrobenzene needed is found to be decreased by the addition of ethylene glycol. The efficacy of a substance such as nitrobenzene in rendering a varnish homogeneous falls off as the softening point of the alkyd resin is raised. The general value of the softening point should be about 125°C.

Clark<sup>126</sup> found that cellulose-ester films for photographic purposes were obtainable by incorporating compounds such as diphenyl orthophthalate with nitrocellulose. The general method of preparing such a film is illustrated by the following example: 300 to 600 parts of a mixture of acetone and methyl alcohol are incorporated with 100 parts of nitrocellulose, 5 to 100 parts of fusel oil, or normal butyl or isobutyl alcohol, and from 1 to 45 parts of diphenyl orthophthalate. This composition is found to give a flexible film. The use of cellulose ester varnish incorporating 0.25 to 5 per cent glycerol butyl phthalate has been recommended as a protective coating for cellulose nitrate lacquer against the action of light.<sup>126</sup>

Cellulose esters are miscible with glycerol esters of aromatic monobasic acids. Plinatus,<sup>127</sup> in finding a close analogy between the effect of camphor on cellulose esters and that of esters of organic acids, proposed the use of these esters as a substitute for camphor in the manufacture of celluloid. By varying the quantity of the acid ester (benzoic-glycerol esters),<sup>128</sup> products were obtained which were hard and horn-like, of medium hardness or finally, of rubber-like softness. The cellulose esters are mixed with the acid esters and the mixture is worked into a homogeneous mass between heated rollers in a kneading mill. During this process the cellulose esters form a homogeneous solution which afterwards gelatinizes or solidifies. These compounds have been utilized in the production of artificial leather,<sup>129</sup> the gelatinized mixture being applied to a flexible base.

## Chapter 48

### Drying Oil Alkyd Resins Uses As Coatings. Varnishes

The underlying aim of the development of synthetic resin finishes has been, not in the preparation of synthetic substitutes to match natural products, but rather in the production of tough flexible materials without the known shortcomings of the natural resins. The best type of synthetic resin varnish or paint vehicle has been produced by condensing the resin components and the oil acids directly, so that distinct chemical compounds of unique properties are obtained, rather than by the nondescript procedure of dissolving a prepared resin in the drying oil.<sup>1</sup> The chemical processes have the additional advantage of lending themselves to strict control, whereby a high grade of uniformity and reproducibility of material may be achieved.

Alkyd resins of the oxidizing type (see Chapter 44) are made by incorporation of drying oil acids in a glycerol-phthalic anhydride type of resin.<sup>2</sup> This class covers a variety of substances, from hard solids approximating in properties natural resins to viscous liquids resembling drying oils. They may be used alone as the binding medium or may be admixed with other resins, oils, varnishes, or nitrocellulose. Although the consistency, acid number, and certain other properties of the oxidizing resins may vary considerably, the quality of high resistance to weathering is common to all. One factor in attaining durability is the relatively high elasticity of these resins, which is greater than that of other known varnish films of equivalent oil length. This may be seen from the following comparison of the Kauri reduction values of an oxidizing Rezyl with two of the durable phenol-formaldehyde types of resin.<sup>2a</sup>

<i>Material tested</i>	<i>Kauri Reduction Value</i>
Phenol-formaldehyde resin, ester gum modification—12-gallon varnish . . . . .	Below 0
Phenol-formaldehyde resin, unmodified—12-gallon varnish . . . . .	10-20
Rezyl (corresponding to 12-gallon oil length) . . . . .	50-60

Owing to this inherent elasticity, the use of oxidizing oils can be minimized, thereby lessening that slow destructive oxidation which leads to loss of gloss and flexibility.

#### INDUSTRIAL APPLICATION OF OXIDIZING ALKYD RESINS

Oxidizing alkyd resins have found industrial application in a variety of forms, covering a range of hardness, flexibility, and drying characteristics which renders possible their use in almost the entire group of paint products. Certain of the

Ulrich, *Farben-Ztg.*, 1934, 39, 1094; *Chem. Abs.*, 1935, 29, 2859.

<sup>2</sup> Some of the trade names for these types of resin are Rezyl, Glyptal, Dulux and Alkydal.

<sup>2a</sup> T. F. Bradley, *Off. Digest, Fed. Paint, Varnish Prod. Clubs*, 1931, 535.

Rezyls<sup>a</sup> are not miscible with drying oils or with the usual oleo-resinous varnishes, but may be employed in xylol solution. For example, a solution consisting of 60 per cent Rezyl and 40 per cent xylol may be thinned to brushing- or spraying-consistency with equal parts of xylol, dipentene and mineral spirits, or of xylol and turpentine containing 2 per cent of pine oil. The petroleum-tolerance of such Rezyls is low, generally being of the order of 30 per cent or less.

The oil-soluble Rezyls<sup>a</sup> may be dissolved in most types of drying oils in the raw state. However, when the oils are bodied, solubility of the resins decreases. Rezyls of this series have a high petroleum-tolerance also, and can be dissolved directly in petroleum thinners. Hydrogenated petroleum hydrocarbons are much better solvents and compare favorably with coal-tar hydrocarbons.<sup>b</sup> The resins may be treated as varnish gums, and cooked with drying oils to form varnish bases. Thus, Rezyl 110 may be cooked with an equal weight of tung oil for several hours at 190-205°C. Better body and gas-resistance may be obtained by heating to 280°C., but the operation must be carried out rapidly to avoid formation of an insoluble gel. Addition of linseed oil, rosin, ester gum or phenol resins enhances gas-proofness. The oil-treated Rezyls have great flexibility, but are too soft for some purposes.

Carbonate pigments (white lead, whiting and colors based on them) should be avoided, since reaction occurs, with evolution of gas, on storage. Basic pigments, e.g., zinc oxide or chrome orange, thicken to some extent with the harder Rezyls, which have an acid number 45-60, but may be used in any proportion with those Rezyls<sup>a</sup> which have very low acid numbers. Zinc oxide, however, tends to produce hard and brittle films. When alkyd resins are used as pigment vehicles in enamels, care must be exercised to avoid contamination with varnish and oil products, or undue exposure to the air, during the grinding process.

The commercially produced oil-soluble Rezyls are used as paint vehicles both in paints where the Rezyl is the sole film-forming binder, and also in conjunction with drying oils. Paints of the latter type have improved working qualities and a wide range of application. An example of a quick-drying Rezyl paint vehicle is:<sup>c</sup>

Rezyl 110. . . . .	105 lbs.
Xylol or turpentine. . . . .	45 lbs.
Mineral spirits . . . . .	100 lbs.
Lead linoleate . . . . .	2 lbs.
Cobalt linoleate. . . . .	$\frac{1}{4}$ lb.

Oxidizing Rezyls have found use also in the replacement of a part, or all, of the bodied linseed oil in printing inks. For this purpose the softer, mineral spirit-soluble resins are best. Quicker drying and a better gloss are obtained as well as better color-retention and resistance to grease and wax. Rezyls may be mixed also with overprint varnish for improved elasticity and adhesion.

The durability of oxidizing alkyd resins, when used in quick-drying house paints, compares very favorably with that of Amberol or ester gum spar varnishes.<sup>d</sup> Test panels, treated with a clear film of hard, medium or soft linseed fatty acid-glycerol phthalate resins, showed perfect condition after 10 months exposure, while similar panels treated with a 46 gal. F7 Amberol spar varnish, and with

Assoc.*, 1930, 370, 437; *Am. Paint J.*, 1930, 14 (52A), 31; *Paint, Oil, Chem. Rev.*, 1930, 90 (17), 84.

a 53 gal. ester gum varnish, failed completely. In paints composed of a variety of pigment mixtures, those with a linseed fatty acid-glycerol phthalate vehicle proved superior to the corresponding standard linseed oil paints. An alkyd resin film (modified by tung oil) on food containers and posters proved to be durable and non-yellowing under tropical conditions.<sup>9</sup>

Windsor<sup>10</sup> has discussed the outstanding advantages of synthetic resin enamels over oil enamels and has reviewed the influence of various factors, viz., time of setting up before baking, minimum baking time, and baking temperature in obtaining the most desirable properties such as hardness, flexibility, alkali- and acid-resistance.<sup>11</sup>

#### FILM-FORMING PROPERTIES OF OXIDIZING RESINS

The film-forming properties of alkyd resins have been studied by Kienle and Ferguson.<sup>12</sup> These workers distinguish three classes of resin: non-convertible, heat-convertible, and oxygen-convertible. Solutions of heat-convertible resins are transformed to the hard, insoluble form by baking. Oxygen-convertible resins (e.g., oxidizing alkyds) require only exposure to the air, the action of heat being merely to assist the oxidation, as with oil-base varnishes. At any one temperature, the oxidizing resins are transformed much more rapidly than the heat-convertible resins. Esters, acetone, or alcohol-mineral naphtha mixtures are solvents for the drying alkyds, and the solutions permit of considerable dilution with aliphatic hydrocarbons. Films formed are very adherent and smooth, with a rapid initial hardening. They possess essentially the same properties as the films from heat-convertible alkyd resins, with an additional pronounced film-building characteristic.

In order to get the best film, it is important that oxidizing alkyd resins should not contain any large amount of free fatty acids. In contrast with drying oils and oxidizing alkyds, the free fatty acids of drying oils do not dry when exposed to the air. They oxidize readily but do not form tough films. The behavior of free unsaturated acids was studied by Eibner and Jung<sup>13</sup> who found that films of acids containing many double bonds oxidize faster than those with few, but are less stable towards water. When mixed with red lead or white lead to form a paint, the acids yield a film in 1-4 days, also when exposed to water they show increasing susceptibility with increase in the number of non-conjugated double bonds.  $\alpha$ -Linolenic acid was found to oxidize in 8-10 days to a film tougher than that from linoleic acid. It yellowed more in winter than in summer and browned at 100°C.  $\alpha$ -Eleostearic acid oxidized in 6-8 days and turned less yellow than the linolenic acid film. It yellowed strongly in the oven, and showed poor adhesion to glass. Clupanodonic acid, with 4 double bonds, oxidized rapidly, browning at room temperature and, as follows from the high unsaturation, was the least stable towards water of all the films examined.

Gelation of oils during bodying is accelerated by a supply of energy in the form of heat, light, or electrical activation.<sup>14</sup> The phenomenon of gelation may oc-

<sup>9</sup> H. Nolte, *Farbe u. Lack*, 1933, 559, 569, 593, 605; *Brit. Chem. Abs. B*, 1934, 210.

<sup>14</sup> J. S. Long and W. S. W. McCarter, *Ind. Eng. Chem.*, 1931, 23, 798.

cur also at room temperature under the influence of high pressures, or in the presence of metallic chlorides. Oxidation is a contributory cause and metallic driers function as catalysts not only of the oxidation reaction, but also of polymerization directly. According to Kienle,<sup>15</sup> the actual mechanism of gelation of synthetic resins is still uncertain. The chemical view of polymerization, whereby molecules are linked by primary valence-forces, applies successfully to many types of resin.<sup>15a</sup> Where straight-chain unions occur, non-convertible polymers are formed; where intertwining branched chains can result, the polymers are convertible. In general there will be obtained a mixture of polymers, in which small molecules of low degrees of condensation are associated with highly polymerized macromolecules. This leads to the formation of a colloidal system, and permits depolymerization, or reformation of a sol system, on appropriate treatment with a solvent. Thus, sols may be prepared from cured alkyd resins, or heat-converted drying oils, by simple prolonged treatment with a solvent in an autoclave. Clear transparent sols of cured glycerol phthalate in glycol diacetate, and of linseed oil gel in benzyl benzoate or petroleum ether have been prepared in this way. While the primary-valence theory of polymerization accounts for most classes of resin gelation, it is possible that in some instances the process must be attributed to association through secondary valences.

#### OXIDIZING ALKYDS AS PAINT VEHICLES

Comparison of drying alkyd type compositions with quick-drying paints (based on bodied tung oil-linseed oil mixtures) indicates that the widest application of the former may be in solid colors, but adverse aging phenomena show the need for precautions in manufacturing such colors.<sup>16</sup>

Schmutz, Palmer and Kittelberger,<sup>17</sup> studying the abnormal failure of paints due to poor bonding between the paint and the wood, have found that varnish in the priming coat affords much greater adhesion than the customary vehicles, regardless of the type of pigment used. A 100 per cent synthetic resin varnish as primer showed very favorable properties, though surpassed by 100 per cent spar varnish.

Mileti and Eddy<sup>18</sup> state that alkyd resin paints give an appearance superior to that of linseed oil paints, but are harder to apply. The linseed oil paints are exceeded in durability only by the paints derived from soft alkyd resins. The volume ratio of pigment had no influence upon durability, but only small amounts of basic pigments (e.g., zinc oxide) should be incorporated in alkyd paints to avoid livering. White and light-tinted alkyd paints are said to have a tendency to chalk, which may limit the use of alkyd resins as a paint vehicle to paints containing unreduced colored pigments.<sup>19</sup> Antimony oxide appears to be the best pigment when an alkyd resin paint is to be tinted. The resulting paint is equal to standard linseed oil paint.<sup>20</sup>

Gardner and Hart in a series of tests on quick-drying, faintly tinted house paints found that linseed oil paints did not possess as good color-retention as

<sup>15</sup> R. H. Kienle, *Ind. Eng. Chem.*, 1931, 23, 1260.

<sup>20</sup> *Circ. Nat. Paint Varnish, and Lacquer Assoc.*, 1934, 471, 339; *Brit. Chem. Abs. B*, 1935, 31.

glycerol-phthalate vehicles.<sup>21</sup> These workers also noted that alkyd coatings chalked less but that some cracked more than bodied tung oil finishes.<sup>22</sup> Further experiments by Gardner and Hart<sup>23</sup> on quick-drying house paints gave good results. A number of mixtures of white lead, zinc oxide, and titanium oxide with a glycerol-phthalic anhydride vehicle successfully withstood exposure to the weather.

When there is a higher-boiling solvent in the diluent, the alkyd resin forms a harder film. However, with a slow evaporation rate the film has an opportunity to oxidize considerably. If certain solvents (e.g., petroleum hydrocarbons) are still present by the time the film has partially oxidized, precipitation and consequent loss of gloss may occur. This may be prevented by addition of eugenol, creosol, or guaiacol as oxidation inhibitors.<sup>24</sup> The addition of 1 per cent of benzoic, salicylic or  $\alpha$ -crotonic acids to linseed oil paint, a four-hour enamel and a bodied oil enamel<sup>25</sup> led to an increase in gloss, the effect being greatest with benzoic acid. However the influence of the acids upon skinning, settling, and yellowing of the film was not uniform.

Hardening of oxidizing alkyd resins, like that of drying oils, is accelerated by metallic driers. These are added in the form of solutions of metallic soaps (linoleates or naphthenates) in mineral spirits or turpentine.<sup>26</sup> Compositions containing driers should not be cooked with the phthalic resins as insoluble compounds are formed. Resinate driers tend to reduce elasticity and durability, and cause greater yellowing of the film than do the linoleate types. Different metals vary in their drying effects, thus zinc has a hardening effect, and may be used in combination with cobalt in baking enamels to secure good drying without surface wrinkling.

Alkyd resins are usable as vehicles for the preparation of rust-preventing paints by incorporation with certain pigments. A study of rust-inhibitive primers on steel panels over a period of 3 months showed the alkyd-zinc chromate formulation to be best.<sup>27</sup> The use of an alkyd resin modified by drying oils as the undercoat has been proposed<sup>28</sup> for places where nitrocellulose lacquers are to be the final coat. White lead, red lead, basic lead chromate and zinc chromate are mentioned as good pigments for these primers.<sup>29</sup>

Coating compositions suitable for intermediate coats on automobile bodies have been made, using pigments and a polymerized binder of the drying-alkyd type.<sup>30</sup> When the oil content is not less than 23 per cent, the resin may be used as a binder in a coating composition for the application of a plurality of coats which dry as a unit. There is no intermediary baking; a certain time is allowed, however, to permit the volatile solvents of one coat to evaporate before the next coating is applied. All the coats dry in a single baking operation to a state which

permits sanding.<sup>31</sup> A ground coat of vitreous enamel on steel or iron forms a good primer upon which to apply synthetic resin enamels.<sup>32</sup> Metal used in the construction of cans may be coated with an alkyd resin composition, it being possible to bake the coat on the metal before the cans are constructed.<sup>33</sup> A wire-enamel, said to form a uniform film quickly, is obtained by dissolving an alkyd resin in a hydrogenated petroleum product.<sup>34</sup>

Oil paints may be improved by having 10 per cent oil-soluble alkyd resin incorporated in them.<sup>34</sup> Coating compositions for outside use, of high durability and having a high percentage of pigment, have been made by employing alkyds of low acid number.<sup>35</sup> Thus a resin of acid number 2.5 is made from 13.43 parts of glycerol, 72.06 parts of linseed oil acids and 14.51 parts of phthalic anhydride. One hundred parts of resin are used with 101 parts of barium-base titanium oxide pigment, 39.4 parts of lithopone, 15.6 parts of zinc oxide, 0.8 part of cobalt-manganese drier and 62 parts of mineral spirits thinner. Other mixed or single pigments and variations in the composition of the resins may be introduced. The chalking-tendency of the titanium oxide is considerably reduced, allowing its use as a chief pigment.

Antimony oxide in mixed-pigment paints of this kind<sup>36</sup> eliminates the chalking tendency, permitting the formulation of non-fading colored titanium oxide coating compositions. Barium titanate used as a pigment in these compositions has good binding power.<sup>37</sup> By lowering the acid number of the alkyd, zinc oxide may be used as the principal pigment constituent.<sup>38</sup> With resins containing less than 35 per cent of drying oil acids, the acid number should be below 30. Highly leaded zinc oxides in Rezyl vehicles are said to have unusual gloss-retention.

As has been stated in Chapter 47, alkyd resins in cellulose ester compositions protect the latter from the discoloring effects of ultraviolet light. This principle has been applied to the production of non-discoloring sheets of pyroxylin plastic compositions. Both sides of the plastic are coated with a transparent oil-resin varnish for the purpose of absorbing actinic rays.<sup>39</sup> Sheets of cellophane may be bonded by an alkyd resin and coated with an insulating varnish to produce an electric-insulating material.<sup>40</sup> An alkyd resin, modified by perilla oil, applied to cellophane forms a base upon which a moisture-proof coating can be applied.<sup>41</sup>

Water paints containing an oily alkyd resin modified with linseed oil acids were proposed by Ott and Breyer.<sup>42</sup> The resin was mixed with ferric oxide and emulsified in water containing casein, ammonia and borax.

Light-colored coating compositions have been produced from oil-modified alkyd

<sup>43</sup> K. Ott and B. Breyer, German P. 599,311, 1934, to I. G. Farbenind. A.-G.; *Chem. Abs.*, 1934, 28, 6001.

resins with an organic peroxide as drier.<sup>43</sup> The oil glyceride present in the resin should not exceed 65 per cent, if slow drying is to be avoided. Treatment of lithopone with acetic acid prevents thickening of enamels made from oil-treated alkyds.<sup>44</sup>

Resins modified with a large proportion of linseed oil acids or other drying oil acids have been applied to the preparation of white enamels,<sup>45</sup> in conjunction with low-viscosity nitrocellulose. Alkyd resins in striping enamels contain more than 50 per cent of drying oil fatty acids.<sup>46</sup>

Leather can be finished off with an oil-modified Glyptal; it is first coated with a mixture of bodied linseed oil in which is incorporated pigments. This is followed by coats of bodied linseed oil thinned with naphtha and then the final coat of resin is dried on at 150-175°F. for 10-20 hours.<sup>47</sup> A varnish for flexible floor coverings can be made by heating a drying-oil resin with a bodied drying oil.<sup>48</sup> A proposed high-glaze finish for fabrics consists of drying oils with a polyhydric alcohol-polybasic acid resin, driers, and a solvent (toluol). This final coating is applied over a cellulose nitrate undercoat.<sup>49</sup>

Coating or finishing compositions for rubber or rubberized cloth<sup>50</sup> have been prepared from alkyd resins modified with drying, semi-drying or fatty oils (e.g., castor oil) or the acids produced on their hydrolysis. Phenol-formaldehyde resins, cellulose esters and plasticizers may be added. Likewise a drying oil-modified alkyd resin-asphalt varnish has been suggested for the purpose.<sup>51</sup> Another use of this varnish is its application to uncured rubber which is then baked to secure an artificial leather.<sup>52</sup> Alkyd resins modified with boiled tung oil may be employed in crystallizing-varnishes for the production of frosted films.<sup>53</sup>

Alkyd resins containing at least one free hydroxyl group and which dissolve or swell strongly in benzene hydrocarbons may be admixed with cellulose ethers to give varnishes or mastics.<sup>54</sup> Thus ethyl cellulose, and the condensation product of phthalic acid and linoleic glyceride, containing unesterified groups, are dissolved in a benzene-toluene-alcohol mixture, yielding a varnish which is a prospective coating for wood. The alkyd resins modified with a monobasic acid (e.g., linseed oil acid), but containing no excess of the acid, are employed for the production of varnishes.<sup>55</sup> Incorporation of 5 per cent  $\alpha$ -unsaturated aliphatic carboxylic acids

<sup>55</sup> K. Ott, H. Bernard and F. Frick, Canadian P. 308,131, 1931, to I. G. Farbenind. A.-G.

(e.g., crotonic or sorbic acid) improves the flowing qualities.<sup>56</sup> Drying alkyds may be dissolved and mixed with colors to form fast-drying inks for offset or intaglio printing.<sup>57</sup> A glycerol-phthalic anhydride drying-oil resin has been utilized in making printing enamel.<sup>58</sup>

Adams<sup>59</sup> described the preparation of metallic paints by suspending metal powders (such as aluminum, copper alloys or silver) in a vehicle consisting of a drying alkyd in a volatile solvent. Paints containing zinc or aluminum may be applied to metals (e.g., iron or copper) and alloy formation effected by heating the metal surface. Metallic flakes in quick-drying varnishes composed of an alkyd resin modified by linseed and tung oils have improved "leafing" properties.<sup>60</sup>

Laborious finishing processes whereby spray-coated articles must be sanded by hand and finished with a spray mist of lacquer thinner may be obviated by subjecting the film to heat so that abrasive marks will be eliminated. The film should contain substances softening under heat-treatment without harmful physical alteration, so that surface flowing is achieved. The presence of oxygen leads to oxidation and subsequent hardening of the film. Lacquers containing drying alkyds are suitable for such treatment, the sanded film being heated at 70-120°C. An example of a suggested composition contains 1.82 per cent nitrocellulose, 23.27 per cent glycerol-phthalic-linseed oil acid resin, 0.91 per cent carbon black pigment, and 74.00 per cent lacquer thinner.

A non-caking pigmented coating can be prepared from a pigment ground in a gasoline solution of rubber to which an alkyd-type resin has been added.<sup>61</sup> Root<sup>62</sup> suggested that a phthalic anhydride-glycerol-linseed oil resin be employed in coating compositions for producing wrinkled finishes on metal. In this type of varnish, it has been generally considered essential to use a varnish resin in a drying oil that will wrinkle on oxidation. However, by using an alkyd resin modified with linseed oil acids, the resin needs only to be dissolved in volatile solvents (e.g., toluol, xylol, naphtha) to give a composition that wrinkles upon baking.

## Chapter 49

### Alkyd Resins in Molding Compositions

Alkyd resins are much less widely employed as binders to form molded articles than in coating compositions. The reason for this is that conversion to the infusible insoluble form is very slow in comparison with the transformation of other synthetic resins generally used for this purpose (urea-formaldehyde and phenol-formaldehyde). Also, since the hardening reaction is probably one of further interesterification of the molecules of the intermediate resin, considerable water vapor is evolved, which tends to form bubbles in the mass. In thin films (e.g., baked coatings) the water readily escapes and high temperatures can be used without disrupting the physical continuity of the resin layer, but in massive form heating must be carried out at a low temperature to allow slow diffusion of water vapor. This low-temperature curing requires inordinately long baking periods<sup>1</sup> and limits the use of heat-hardening alkyd resins to certain special fields where particular properties of the hardened resin give it a distinct advantage.

With alkyd resins of the fusible soluble variety the same considerations hold in regard to their use in molded materials. They must compete with cheaper thermoplastic substances and consequently are successfully used from an economic standpoint only in applications where some particular property of the resins comes into play (e.g., high compatibility with nitrocellulose).

It is possible to accelerate the transformation to the infusible form. For example, a mixture of three mols of phthalic anhydride and two mols of glycerol is suddenly transformed at 235-240°C. from a liquid to a spongy solid, which is quite insoluble in ordinary solvents. A number of substances (e.g., zinc oxide, calcium oxide, barium carbonate or barium hydroxide) lower the temperature at which solidification occurs.<sup>2</sup> This result is probably due to the phthalate salt formed.<sup>3</sup> Ammonium persulphate also has a marked catalytic action on the solidification step. For example, an agitated mixture of 2.7 parts of phthalic anhydride and 1 part of glycerol would normally solidify at 235-240°C. but, if ammonium persulphate is added to the batch held at 140-145°C., the mass becomes too viscous to be stirred. Bleaching powder causes conversion of the same phthalic anhydride-glycerol mixture at 165°C. Uranium nitrate, ammonium bisulphate or zinc chloride yielded a rubbery compound at 155°C.

Silicotungstic acid in the proportion of 10 per cent exerts a vigorous action at 115-125°C.; 4 per cent of this compound brings about solidification at 155°C. A resin, prepared from equimolecular proportions of glycerol and phthalic anhydride but heated only to 232°C. to avoid transformation to the insoluble heat-resistant form, was found to harden quickly on the hot plate after admixture

<sup>1</sup> To obtain light-colored slabs of phthalic anhydride-glycerol resins free of bubbles, J. H. Schmidt (U. S. P. 1,663,133, Mar. 20, 1928, to Bakelite Corp.; *Chem. Abs.*, 1928, 22, 1696) found it necessary to subject the initial reaction product to a temperature of 125° C. for a period of several weeks.

<sup>2</sup> Carleton Ellis, U. S. P. 1,897,977 and 1,897,978, Feb. 14, 1933, to Ellis-Foster Co.; *Brit. Chem. Abs. B*, 1933, 978.

<sup>3</sup> It is noteworthy in this connection that the addition of soaps in small proportions (0.1 per cent), especially the fatty acid salts of aluminum, tin, zinc and magnesium, accelerates the esterification of higher fatty acids with polyhydric alcohols. British P. 302,411, 1927, to I. G. Farbenind. A.-G.; *Brit. Chem. Abs. B*, 1929, 235.

with silicotungstic acid. Wright<sup>4</sup> added dehydration catalysts (e.g., oxides of calcium, magnesium and zinc or finely divided iron and zinc) to aid the transformation to an infusible stage.

#### MOLDED PRODUCTS

The general properties of alkyd resins have led to efforts to utilize them in the manufacture of molded products. One method makes use of a resin prepared from glycerol and one or more polybasic acids, with cellulose esters or cellulose ethers for strengthening and toughening the products.<sup>5</sup> Resins may be obtained, for example, by heating a mixture of glycerol, salicylic acid and phthalic anhydride to a temperature of approximately 290°C. The temperature is raised slowly, and the product is cooled under reduced pressure to remove as much as possible of unused acid. This treatment also aids in the production of light-colored resins.

Generally the acid number of a resin should be as low as 20 if nitrocellulose is to be incorporated, and this can be obtained by the use of excess glycerol, by protracted heating at 200-300°C. or by adding an aromatic amine (aniline or toluidine).<sup>6</sup> In addition to nitrocellulose, the resin may be mixed with fillers (e.g., lampblack, asbestos, mica dust). The compositions are rendered plastic by warming, placed in a mold and pressed while chilling.<sup>7</sup> The following example illustrates the proportions employed:

	Parts by Weight
Mica dust . . . . .	12
Terra alba . . . . .	8
Rosin phthalic glyceride resin . . . . .	8
Nitrocellulose . . . . .	2
Asbestos fiber . . . . .	1
Lampblack . . . . .	1

Nitrocellulose, up to 10 per cent, increases the strength of the final product but further additions do not give proportionate results.

Cold-molded articles may be produced from a mixture of asbestos fiber and other mineral fillers with an alkyd resin. The addition of 1-2 per cent of a drying oil (tung oil) is advantageous. The cold-molded article is air-dried for 24 hours, after which the temperature is raised to 70°C. for 5-6 hours. It is then baked for 30 minutes at 150-180°C. and finally at 290-300°C. for 0.5-1 hour. A typical resin for use in this connection is made by heating 100 parts of rosin, 21 parts of phthalic anhydride and 24 parts of glycerol at 280-290°C. The phthalic anhydride may be replaced by citric, tartaric, malic, maleic or succinic acids, or their anhydrides.<sup>8</sup>

Wright<sup>9</sup> produced a molding composition by heating the alkyd resin already in the B stage with a swelling agent (e.g., acetone) in the presence of a plasticizer (e.g., vinyl chloride or tolyl phosphate). Extrudable compositions may be formed by working between hot rollers a mixture of 3 parts of the totally cured resin and 1 part of the same resin in the uncured or semi-cured state.<sup>10</sup> Zinc oxide or other basic materials hasten the curing process.

## MOLDED MICA PRODUCTS

The excellent electrical resistance of sheet mica combined with high mechanical strength and heat-resistant properties has resulted in its use in the manufacture of electrical machinery from the earliest days of the industry. The scarcity of large sheets of mica and the high price of such material have given rise to the development of a large industry for the manufacture of composite sheets from flake mica, mica waste, split mica and mica powder, since these materials are abundant and cheap.<sup>11</sup>

An early method of producing composite mica sheets was developed by Lee.<sup>12</sup> He incorporated the mica with shellac by heating. Dyer<sup>13</sup> used shellac varnish for this purpose. Flakes are coated with varnish, allowed to dry and pressed together under heat. When used in commutator construction, mica plates or cones are liable to become sufficiently heated for shellac to soften, which causes carbonization and short circuits. Attempts to overcome this difficulty by the use of phenol-aldehyde resins have shown that these also carbonize readily and, moreover, they do not adhere well to mica. Alkyd resins, on the other hand, appear to satisfy the requirements of a bonding agent for mica and have been used for this purpose. Such mica compositions have a high electrical strength, the value for alkyd composite sheets being higher than for shellac-bonded mica. The power factor (see Chapter 69) of properly made alkyd-cemented mica at 100 kilocycles is given as 1.95, as compared with 4.6 for the shellac-bonded product.<sup>14</sup> Properly cured alkyd-treated sheets yield less under mechanical compression and are more flexible than the shellac-bonded material.

Barringer and Peterson<sup>15</sup> prepared a laminated mica product by treating mica flakes or plates with an acetone solution of the alkyd resin, evaporating the solvent and heating the composition at 175°C. until the binder is in an intermediate plastic state. The product then is molded at 250°C., hardened at 300°C. and cooled under pressure. The procedure may be modified<sup>16</sup> by carrying out the first stage of the curing under reduced pressure to facilitate removal of solvent and volatile reaction products. Mica plates are pasted together as before with the solution of an alkyd resin in acetone. The built-up sheets are covered on both sides with dry mica to prevent sticking to the supports and are heated in an evacuated oven at 110°C. for 0.5-2 hours. Acetone is completely removed in the process and some preliminary polymerization of the resin occurs. During further curing of the material at 160-170°C. an intermittent pressure is applied, the release of the pressure providing for the escape of evolved gases. The final heat treatment is carried out as described above.

Coffey<sup>17</sup> found that thin mica splittings can be cemented together with a condensation product of glycerol and phenol and molded under pressure. Five parts by weight of the resin are used with 95 parts of mica. The hot material may be molded into shapes which retain their form when cooled. Coffey also described a commutator ring the outer layer of which consists of mica plate prepared by cementing mica flakes with alkyd resin, and the inner layer composed of asbestos impregnated with shellac.<sup>18</sup> Asbestos gives to the material a certain resiliency

<sup>11</sup> A historical survey of the early development in this field is given by J. Roseman, *Plastics*, 1928, 4, 549.

<sup>18</sup> J. M. Coffey, U. S. P. 1,857,586, May 10, 1932, to Mica Insulator Co.; *Chem. Abs.*, 1932, 26, 3860.

which causes the ring to conform more readily to irregularities in shape of the commutator copper bars, and thus permits a tight connection.

Frederick<sup>19</sup> used both shellac and alkyd resin in making mica sheets. The sheet is formed from a mixture of mica with shellac and then coated with an alkyd resin. The whole mass is subjected to heat to amalgamate the shellac with alkyd resin and to change the latter to the infusible state.

Single sheets of mica may be covered with a mixture of an alkyd resin and a vapor-adsorbing filler (e.g., asbestos, iron oxide, kieselguhr or talc) and then the resin is hardened by heating under pressure.<sup>20</sup> Insulators are made by cementing sheets of mica with a resin prepared from polyhydric alcohols and dicarboxylic acids of the type of diglycolic.<sup>21</sup> The resin derived from glycerol and phthalic anhydride modified with drying oil, or drying oil acids, may be used.<sup>22</sup> Weber suggested bonding mica flakes with a mixture of an alkyd resin, an aromatic phosphate plasticizer and a glue.<sup>23</sup> The composite article is consolidated by heating under pressure at 250°C.<sup>24</sup>

#### FLOOR AND WALL COVERINGS

The addition of alkyd resins to flooring compositions has been proposed because the resins form flexible final products. Increased flexibility in a floor covering would mean that such rugs would lie flatter. One application of this type<sup>25</sup> relates to a duplex floor covering consisting of a saturated felt base and a tread-veneer of resin-nitrocellulose composition. The plastic coating compositions are obtained by dissolving nitrocellulose, alkyd resin and plasticizing materials in volatile solvents. The product is mixed with ground cork and fireproofing agents (e.g., powdered gypsum or magnesium carbonate). This agglomeration is put through a sheeting machine, deposited on the felt and dried.

One resin that may be used in the coating composition is prepared by heating to 290°C. a mixture of rosin (100 parts), phthalic anhydride (50 parts) and glycerol (48 parts). The following formula will illustrate the type of composition and proportions by weight: nitrocellulose (40 parts), rosin ester (40 parts), castor oil (58 parts), tricresyl phosphate (15 parts), powdered gypsum (300 parts), ground cork (100 parts), pigment (10 parts) and solvent (80 parts). Volatile solvents (acetone, methyl alcohol or isopropyl alcohol) that do not dissolve the asphalt of the felt are preferable.<sup>26</sup>

If a thicker product is desired more layers of tread can be added to the covering. When high-boiling solvents are used in conjunction with multiple layers, the time of drying is increased to the point where the cost of manufacture would be high. On the other hand, employment of volatile solvents alone results in rapid evaporation during the sheeting process. To make possible the use of volatile solvents, wax (e.g., paraffin, carnauba or montan) is added to the flooring composition. This retards evaporation at room temperatures without interfering with

<sup>19</sup> L. T. Frederick, U. S. P. 1,873,753, Aug. 23, 1932, to Continental Diamond Fibre Co.; *Chem. Abs.*, 1932, 26, 6083.

<sup>23</sup> H. C. P. Weber, U. S. P. 1,928,718, March 10, 1933, to Westinghouse Elec. and Mfg. Co.; *Chem. Abs.*, 1933, 27, 5847.

<sup>24</sup> C. D. Hoeker (U. S. P. 1,512,024, Oct. 21, 1925; *Chem. Abs.*, 1925, 19, 710) obtained a moldable composition for electrical insulation by mixing mica with the reaction product formed by heating castor oil to the point of partial carbonization. In place of castor oil other substances capable of yielding glycerol and an organic acid were suggested.

<sup>25</sup> Carleton Ellis, U. S. P. 1,784,135, Dec. 9, 1930, to Ellis-Foster Co.; *Chem. Abs.*, 1931, 25, 435.

<sup>26</sup> For the inclusion of alkyd resins in flooring compositions for use with paper base see Carleton Ellis, U. S. P. 1,784,799, Dec. 9, 1930, to Ellis-Foster Co.; *Chem. Abs.*, 1931, 25, 435.

the final drying operation. The wax also facilitates the printing of a design on the surface of the floor covering.<sup>27</sup>

The inclusion of lithopone, white lead, lead sulphate, baryta and chalk in the alkyd-nitrocellulose coating produces a white finish. Small masses of intense colors introduced onto the white sheeting yield variegated color effects, and cotton linters incorporated into the surface give a white textured effect.<sup>28</sup>

Nitrocellulose and wax are considered to be incompatible but Lougovoy<sup>29</sup> has developed a nitrocellulose tread coating which adhered well to paper waterproofed with a high proportion of wax. The following example will serve to illustrate the type of composite utilized:

	Parts by Weight
Cleaned motion-picture film . . . . .	200
Acetone . . . . .	300
Benzol . . . . .	150
Tricresyl phosphate . . . . .	130
Blown castor oil . . . . .	130
Denatured alcohol . . . . .	50
Paraffin wax . . . . .	10
Benzoic-phthalic-glyceride resm . . . . .	60
Rosin . . . . .	40

This composition was thoroughly mixed and to it was added:

	Parts by Weight
Vegetable-ivory sawdust . . . . .	130
Wood flour . . . . .	100
Perhydrated calcium sulphate . . . . .	200
Lithopone . . . . .	200
Diphenylamine . . . . .	5
Pigment . . . . .	3

The plastic composition was sheeted onto a paper base containing paraffin wax.

The author<sup>30</sup> has also employed acetone-soluble cellulose acetate with alkyd resins to prepare a non-curling floor covering. The alkyd resins are incorporated with cellulose acetate, solvents, wax, fillers and pigments, and sheeted onto an asphalt-saturated felt base. The proportion of resin in this flooring composition should not exceed the proportion of cellulose acetate. The resins proposed<sup>31</sup> for use with nitrocellulose are linseed-phthalic glyceride, cottonseed-phthalic glyceride, blown rapeseed-phthalic glyceride, soya bean-phthalic glyceride, benzoic-phthalic glyceride and castor oil-glycerol or -glycol phthalate. The following example illustrates the preparation of these resins: Glycerol (94 parts by weight), phthalic anhydride (160 parts by weight) and fatty acids of linseed oil (80 parts by weight) are heated to 250°C. for two hours.

Phelan<sup>32</sup> has described an adhesive backing (for inlaid linoleum) prepared by coating a saturated felt base with an alkyd resin paint. The latter is made by heating at 150-180°C. a mixture of 35 parts of ethylene glycol, 3.5-7.5 parts of diethylene glycol, 8-13 parts of glycerol, 105 parts of phthalic anhydride and 30 parts of drying oil acids, and dissolving the product in ethylene glycol monoethyl ether. A floor-covering material is obtained by impregnating a felt base with a bituminous saturant, covering it with a sealing coat containing an alkyd resin and finally applying a decorative coating over the sealing coating. One advantage

of an alkyd resin is that it does not dissolve the bituminous material.<sup>33</sup> Sheet material, for floor coverings, gaskets and artificial leather, is obtained by felting together layers of comminuted cork or fibers that are saturated with an alkyd resin binder.<sup>34</sup>

#### ALKYD RESINS IN THE RUBBER INDUSTRY

During the process of vulcanization, the outer layer of rubber is likely to be overcured before the whole mass is vulcanized. This phenomenon is called scorching and is overcome in part by the addition of substances called scorch-retarders. The usefulness of alkyd resins as scorch-retarders has been investigated by Thies.<sup>35</sup> Glyceryl phthalate was an effective agent, but it interfered with curing if more than 0.25 per cent was added to the rubber. In such small amounts it is not as efficient as zinc resinate or benzoic acid.

Tendencies to pre-vulcanization, especially with accelerators of the 2-mercaptarylenethiazole type, are overcome by incorporating in the rubber mixture a condensation product of the polyhydric alcohol-polybasic aromatic acid class of acid value 100-150.<sup>36</sup> The resin not only modifies the rate of vulcanization but gives products which have satisfactory qualities with respect to aging, flexing and abrasion. It has also been found that the strength of vulcanized natural or synthetic rubber is enhanced by the addition of such resins.<sup>37</sup> The resistance of rubber to oil is increased by the incorporation of a large proportion of an alkyd resin.<sup>38</sup> The materials from which the alkyd resins are prepared may be added directly to a vulcanizable rubber mix.<sup>39</sup> A plastic rubber composition, which is resistant to hydrocarbons, is made by including an alkyd resin with the latex. The latex is mixed with the resin dissolved in 5 per cent ammonia, and the final product precipitated by the addition of acetic acid.<sup>40</sup>

Naunton and Siddle<sup>41</sup> report that lacquers prepared from alkyd resins are superior in several respects to nitrocellulose and oil varnishes for coating rubber goods. The film is hard, glossy and flexible and can be cold-vulcanized with sulphur monochloride. The gas-retaining property of heat-vulcanized rubber is improved by applying a composition composed of an alkyd resin, glycerol and gelatin. Alternatively, the rubber may be coated before vulcanization.<sup>42</sup>

Drummond<sup>43</sup> is of the opinion that alkyd resins last longer than rubber where exceptional resistance to heat and chemical action is required.

#### ELECTRICAL INSULATION

Laminated products for use in oil-filled electrical apparatus have been described by Segar.<sup>44</sup> The fibrous material is impregnated and bonded with a composition

<sup>44</sup> H. D. Segar, U. S. P. 1,899,591, Feb. 23, 1933, to General Electric Co.; *Chem. Abs.*, 1933, 27, 3018.

containing equal parts by weight of shellac and an alkyd resin modified with drying oil acids.

A cable insulated with alkyd-treated cloth capable of resisting oil and withstanding high temperatures has been developed.<sup>43</sup> Although this cloth has a slightly lower dielectric strength than some varnish-treated cloth, its flexibility and toughness will cause it to retain its dielectric strength for a longer time. A suggested wrapping for rubber-coated wire consists of a fabric impregnated with diethylene glycol phthalate.<sup>44</sup>

By coating the outside of a structure composed of fibrous sheets (impregnated with a phenol-formaldehyde resin) with an alkyd resin, electrical arc-resistant materials are obtained.<sup>45</sup>

Safford<sup>46</sup> made insulated electrical coils by extruding a definite thickness of flexible alkyd resin on an electrical conductor, curing the resin, extruding a second layer on the cured coat, winding the conductor so insulated into a coil, pressing the wound coil in a mold and curing the product with heat.

An electrical insulating material may be made from a mixture of a water-insoluble cellulose ether and methylene diaralkyl or diaryl ethers (methylene dibenzyl or diphenyl ethers and their lower alkyl or alkoxy derivatives) and alkyd resins.<sup>47</sup>

A composition proposed by Groten<sup>48</sup> for molded insulation consists of asphalt (gilsonite) and portland cement mixed with an oil-modified alkyd resin dispersed in linseed oil containing copal.

Hovey<sup>49</sup> has used an alkyd resin solution as a temporary binder for inorganic insulating compositions to permit the bending of wire without cracking the insulation. A copper wire is first given a coating of oxide or lead borate followed by a thin coat of alkyd resin. A coil is wound and the resin volatilized by heating 2 hours at 380–400°C. and a final insulation is then applied consisting of mixtures of water glass, asbestos, flint or magnesium oxychloride and other hydraulic cements.

#### ABRASIVES

Resins of the alkyd type, because of their resistance to water, can be utilized as binding agents for abrasants, e.g., alumina, emery and Carborundum.<sup>51</sup> Similar applications are mentioned by Barringer<sup>52</sup> who formed grinding wheels, whetstones, sandpaper and other articles by bonding abrasive grains with the condensation product of a polybasic acid and a polyhydric alcohol. The resin may be powdered, or dissolved in a solvent, before admixture with the abrasive. Plasticizing agents, e.g., indene polymer, tricresyl phosphate, glycol diacetate, triacetin, cumarone resin or pitch, may be added, and the material is molded at 150°C. after

which it is cured by heating without pressure. Alternatively, powdered abrasive material may be applied to cloth or paper coated with a solution of the resin and a plasticizing agent and the resin hardened by heat. Robie<sup>55</sup> used glycerol-phthalic anhydride resin, incorporated with inorganic or organic fillers, as a binder. Novotny<sup>56</sup> prepared an abradant by heating abrasive grains, gum accroides, a phenolic substance, a hardening agent, aldehydes and an alkyd resin.

#### MISCELLANEOUS APPLICATIONS

Alkyd resins are employed in the production of a friction material for brake linings.<sup>55</sup> Layers of asbestos cloth and brass wire are coated with a solution of the phthalic anhydride-glycerol condensation product which may be modified with oleic acid. After drying, the layers are heated and molded under pressure.

Dissolved in a volatile solvent, alkyd resins have been employed to cement sand in preparing a foundry-core composition, which can be hardened by baking. These resins are volatilizable at the temperature of the molten metals used for casting.<sup>56</sup>

Alkyd resins have also been utilized as binders in the manufacture of a hard metal composition (cobalt-tungsten carbide).<sup>57</sup> The method is carried out as follows: A mixture of tungsten with 3-10 per cent of carbon and not more than 25 per cent of cobalt is ground, moistened with acetone and mixed into a stiff paste with 2 per cent of a glycerol-phthalic anhydride resin. The paste is shaped, dried and sintered under pressure at 1375°C. Alternatively, a mixture of 80-97 per cent of tungsten carbide and from 3-20 per cent of cobalt in powder form may be pressed into bars which are sintered at 1375°C.

Rohlf<sup>58</sup> utilized alkyd resins, in the intermediate B stage, for cementing layers of cloth or paper. The alkyd-coated layers are subjected to a pressure of 1000 pounds per square inch at the softening-temperature of the resin, 125-140°C. These conditions are maintained for 14-16 hours to cure the binder without changing the character of the sheet material. A fibrous composition product, applicable as transformer spools, refrigerator trays or door strips, has been made by impregnating layers of interlocked fibers of wet paper pulp with a binder of alkyd resin, drying the mass and molding it under heat and pressure.<sup>59</sup> Dyes, pigments and fillers (e.g., clay, asbestos, mica, talc, silica) may be added. Groff<sup>60</sup> developed a process for making laminated sheets in which paper, cardboard or fabric is impregnated with a solution of an alkyd resin, dried and heated at 110-150°C. until the resin is converted to a tough infusible modification, resistant to water and all ordinary solvents. The sheets are coated by dipping or spraying with a reactive varnish of the phenol-aldehyde type and dried to expel the solvent. The coated sheets are then superposed and consolidated by heat and pressure. Products manufactured in this way are characterized by high shock-resistance and can be used for making silent gearing, piston segments and clutch linings.

Wright<sup>61</sup> produced a molding composition from alkyd resin (10 parts), polymerized vinyl chloride (40 parts), dibutyl phthalate (30 parts), alpha cellulose (7.5 parts) and Titanox (12.5 parts). Switch plates can be made by hot-pressing the resin in a mold whose surface is sprinkled with a finely divided metal, e.g., bronze, copper or aluminum powder, to improve the appearance of the final product.<sup>62</sup> Another method, developed by de Bell,<sup>63</sup> consists in treating a filler with an alkyd resin, after which the material is comminuted, mixed with a phenol-aldehyde product and molded. Montan wax, zinc stearate or other lubricants may be added. Watson<sup>64</sup> molded tubes and spools for electrical appliances from kraft sulphite sheet wood pulp impregnated with shellac, phenol-aldehyde or glycerol-phthalic anhydride resins.<sup>65</sup>

Alkyd or phenol-formaldehyde resins, mixed with high-boiling plasticizers, may be formed into "non-breakable" watch glasses, which are hard at ordinary temperatures, but soften at about 200°C.<sup>66</sup> Such resins may be employed also in the manufacture of spinning-nozzles for artificial silk.<sup>67</sup> Dentures are produced by heating the resin to incipient gelation, molding and converting to the infusible state under pressure at 140-200°C. Heating is continued until the articles are practically non-plastic at 36°C.<sup>68</sup>

Composition tiles for use in refrigerators and in building construction may be formed from asbestos and an inorganic binder, together with a water-impervious, heat-resisting coating of one or more alkyd resins, capable of becoming infusible and insoluble on heating, a plasticizer and an opaque filler.<sup>69</sup> A fire-resisting panel comprised of layers of asbestos with a wood veneer may be constructed by impregnating the layers with an alkyd resin and uniting them under heat and pressure.<sup>70</sup>

Sherburne<sup>71</sup> has described a method of making phonograph needles by impregnating styli of bamboo with a hardened alkyd resin or a mixture of the resin with a drying oil. The glycerol-phthalic anhydride resin has been applied in making sound records.<sup>72</sup> A thin metal disc or metal gauze is coated on one or both sides with the alkyd resin, and an additional thin coating of shellac is applied for receiving the sound-groove impressions. A transparent, flexible, condensation product of a polyhydric alcohol and a polybasic acid is proposed as a base in the making of photographic film.<sup>73</sup> A filler consisting of metal powder, obtained by thermal decomposition of metal carbonyls, has also been used with alkyd resins.<sup>74</sup>

Parchment-like paper may be produced by impregnating (at 140-160°C. for 1-3 minutes) unsized paper with a molten, partly polymerized alkyd resin plasticized with tricresyl phosphate.<sup>76</sup> More complete polymerization is effected by heating for 6 hours at 130°C.

Safford<sup>76</sup> prepared printing and offset rolls by extruding a mixture of cured and uncured alkyd resins, together with a filler (cork, titanium oxide) onto a core and curing the resinous layer by heat.

Synthetic resins from polyhydric alcohols and aliphatic or aromatic dicarboxylic acids have been employed in the manufacture of artificial threads. The resins, together with a softening agent, are dissolved in an organic solvent, e.g., cyclohexanone, and spun into a precipitating-bath containing acetic acid, sodium perchlorate or sodium thiocyanate.<sup>77</sup> The swollen threads are stretched in several increasing steps and then shrunk before collecting on a receiving device.

A metallic mirror for withstanding high temperatures consists of a silver reflecting surface, a coating of copper on the silver, and a backing of an aluminum alloy. The alloy is attached to the copper surface by a cement containing an alkyd resin.<sup>78</sup> A self-lubricating metallic body can be obtained by cementing a paste of graphite onto a metallic surface with an adhesive containing a polyhydric alcohol-polybasic acid resin.<sup>79</sup>

Barringer and Rohlf<sup>80</sup> suggest the following procedure for making laminated glass. A layer of alkyd resin is placed between the glass sheets and a pressure of the order of 50 pounds per square inch is applied at 110°C. for 5 minutes, after which the temperature is lowered to 70-75°C. while the pressure is gradually increased to 200 lbs. The cooling is completed under pressure.

Sheets of cellulose ester and glass can be cemented by the condensation product of a polyhydric alcohol, a polybasic acid and a glycerol ester of a fatty acid.<sup>81</sup> Macht<sup>82</sup> added pyroxylin and a pyroxylin plasticizer to an alkyd resin to form an adhesive for this purpose. Laminated sheets of cellulose esters, used for wrappings or similar purposes, have been made with an alkyd resin as the adhesive for uniting the sheets.<sup>83</sup> In the production of sheet material from urea-aldehyde resins, the incorporation of an alkyd resin is said to increase the stability of the final product.<sup>84</sup>

Hovey<sup>85</sup> mixed from one to two parts of nitrocellulose with a resin made from phthalic anhydride, glycerol, linseed oil fatty acids, ethylene glycol, tung oil and rosin to make a cementing composition.

Alkyd resins are also used in the preparation of a softener for cellulose ester adhesives, e.g., pyroxylin or cellulose acetate cements, used to unite shoe parts.<sup>86</sup> The softener is made by heating diethylene glycol, phthalic anhydride and tung oil under a reflux condenser with agitation.

## Chapter 50

### Miscellaneous Resins Containing Oxygen Linkages

Polyethylene oxides and polyvinyl ethers, described in this chapter, are compounds which structurally resemble cellulose in that they are long, linear molecules (see Chapter 4). Their development as synthetic resins is a recent one, and parallel with technical progress there has been an advance in the elucidation of the constitution of this group of compounds, particularly by Staudinger and his co-workers. The inclusion of polyanhydrides, lactic acid, shellac and carbon suboxide is justified by similarities in the structure of the resinous bodies derived from them.

#### POLYETHYLENE OXIDE AND RELATED COMPOUNDS

Ethylene oxide,  $\begin{array}{c} \text{CH}_2 \\ | \\ \text{CH}_2 \end{array} \text{O}$ , is a liquid boiling at 12.5°C., and characterized by

a very strong tendency to polymerize. It was prepared by Wurtz<sup>1</sup> from ethylene chlorohydrin and caustic potash, and is obtained also directly from silver oxide and ethylene dibromide at 250°C., a method which elucidates the formula of the compound.<sup>2</sup> When heated with water in a closed tube ethylene oxide forms glycol and polyethylene glycols.<sup>3</sup> Staudinger and Schweitzer<sup>4</sup> separated a series of fractions from such a mixture which varied from glycol,  $\text{HOCH}_2\text{CH}_2\text{OH}$ , a heavy liquid boiling at 180°C. to the sixfold polymer,  $\text{HO}(\text{CH}_2\text{CH}_2\text{O})_6\text{H}$ , a very viscous liquid boiling at 325°C. at a pressure of 0.025 mm. Wurtz<sup>2</sup> also obtained a series of polyethylene acetates from the corresponding glycols, but neither the glycols nor the acetates could be isolated in a pure state.

Later, Wurtz<sup>5</sup> observed the formation of a solid ethylene oxide on allowing the monomeric compound to stand in contact with a trace of alkali or zinc chloride. This polymerized oxide melted at 56°C. and was soluble in water and alcohol but insoluble in ether. Roithner<sup>7</sup> noted that reaction took place more rapidly at 50-60°C. in the presence of alkali.

Staudinger and Schweitzer<sup>8</sup> found that polymerization of ethylene oxide with anhydrous stannic chloride occurred readily at -80°C. This agent has a well-established polymerizing action on unsaturated hydrocarbons such as styrene, indene, isoprene, or cyclopentadiene.<sup>9</sup> Metallic sodium or potassium and trimethylamine also were effective catalysts. Reaction with stannic chloride was carried out at low temperatures, as the heat of polymerization (20 to 30 calories per mol) was liberated so rapidly at room temperature that unpolymerized oxide was

suddenly volatilized with the development of extremely high pressures, often resulting in explosions. The product with stannic chloride was divided into a series of fractions by solution in benzene and fractional precipitation with ether. The average molecular weight of the initial material was 3000, and this yielded five fractions ranging in molecular weights from 4650-4900 to 430,440.<sup>10</sup> The melting points and viscosities were lower, and the solubilities in ether higher, for the lower polymers. (See Figure 130.)

The effect of various catalysts on the polymerization of ethylene oxide at 20°C. is given in Table 49.<sup>11</sup>

TABLE 49.—Rate of Polymerization of Ethylene Oxide with Various Catalysts.

Catalyst	Yield of Polymer	Molecular Weight	Time
Trimethylamine, Sodium, Potassium, Stannic chloride } .. . . .	5%	2,000	1-2 weeks
Sodamide. ....	1- 2%	10,000	2-3 months
Zinc oxide .....	10-20%	60,000	3-4 months
Strontium oxide .....	10-20%	100,000	2-3 months
Calcium oxide. ....	50%	120,000	about 2 years

Oxides of iron, magnesium, or lead, silica gel, and activated carbon did not effect polymerization. Aluminum oxide very slowly yielded hemicolloids. Melting points and viscosities increased with the degree of polymerization. Hard products were obtained only when the viscosity was high, such materials possessing the property of yielding tough films. All the polyethylene oxides were shown by x-ray diagrams to be crystalline and viscosity measurements indicated a meandering structure for the molecule.<sup>12</sup>

Propylene oxide also polymerizes with vigor under the influence of stannic chloride. Low (liquid) polymers constitute the main product, but semi-solid polymers may be obtained by fractionation. The latter have a molecular weight of approximately 9000 and are soluble in benzene, whereas polyethylene oxide of the same degree of polymerization is only slightly soluble in benzene and melts at about 60°C.<sup>13</sup> On heating propylene oxide at 117°C. with potassium hydroxide for 12 days a triether,  $C_6H_{12}O_4$  (b.p. 128-130°C. at 2.4 mm.), and a tetramolecular condensation product,  $C_{12}H_{20}O_6$  (b.p. 120-140°C. at 2.4 mm.), are obtained.<sup>14</sup>  $\gamma$ -Phenyl- $\beta$ -benzylpropane- $\beta$ -diol treated with concentrated sulphuric acid at 0°C. yields resinous products only, but on boiling with 20 per cent sulphuric acid or anhydrous oxalic acid,  $\gamma$ -phenyl- $\beta$ -benzyl- $\alpha,\beta$ -propylene oxide (m.p. 78°C.) is formed.<sup>15</sup> The latter proved to be a stable compound which did not isomerize,

<sup>10</sup> R. Signer and H. Gross (*Helv. Chim. Acta*, 1934, 17, 335; *Chem. Abs.*, 1934, 28, 4287) report the molecular weight of polyethylene oxide in ethylene bromide, determined by ultracentrifugal methods, as 70,000.

<sup>11</sup> H. Staudinger and H. Lohmann, *Ann.*, 1933, 505, 41.

<sup>12</sup> The meandering structure of polyethylene oxide may be represented by

See Chapter 4. This type of structure was also indicated by x-ray studies made by E. Sauter, *Z. phys. Chem.*, 1933, 21, 161, 186; *Chem. Abs.*, 1933, 27, 3867.

<sup>14</sup> P. A. Levene and A. Walti, *J. Biol. Chem.*, 1927, 75, 325; *Brit. Chem. Abs. A*, 1927, 1166.

<sup>15</sup> M. Tiffeneau, A. Orékhov and J. Lévy, *Bull. soc. chim.*, 1931, 49 (4), 1840; *Brit. Chem. Abs. A*, 1932, 395.

suggesting that substitution destroys the tendency towards polymerization in this series of oxides.

#### DERIVATIVES OF POLYETHYLENE OXIDE

Polyethylene oxides yield a number of derivatives which differ but little in their physical properties from the corresponding polymerized oxide. Staudinger considers that polyethylene oxide is a dihydrate with the formula  $\text{HOCH}_2\text{CH}_2\text{O}-(\text{CH}_2\text{CH}_2\text{O})_x-\text{CH}_2\text{CH}_2\text{OH}$ . One explanation for the formation of the long chain is as follows: a molecule of ethylene oxide takes up a molecule of water to give glycol, which then reacts with another molecule of the oxide to give a polyglycol. The latter in turn combines with still another molecule of the oxide, thus building up the chain. Acetylation of the polymer transforms it into a diacetate to which is assigned the formula,  $\text{CH}_3\text{COOCH}_2\text{CH}_2\text{O}-(\text{CH}_2\text{CH}_2\text{O})_x-\text{CH}_2\text{CH}_2\text{OOCCH}_3$ . The action of other reagents on the end-groups offers the possibility of introducing various elements into the molecule. Staudinger has used, for example, tri- and

FIG. 130.—Polyethylene Oxide Eucolloid Prepared by H. Staudinger. Molecular Weight About 70,000.

dimethylamine as catalysts in bringing about polymerization, and the resulting material actually contained combined nitrogen.<sup>16</sup> In this instance the initial product was possibly an ethanolamine,  $\text{HOCH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$ , to which another molecule of oxide could add giving the ether,  $\text{HOCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$ . Continuation of such reactions results in long-chain molecules of high molecular weights. Similar explanations are offered by Hibbert and Perry,<sup>17</sup> who also report that polymerization of ethylene oxide in methyl alcohol as a solvent furnishes compounds having methoxy terminal groups.

From ethylene chlorohydrin and ethylene oxide in the molecular ratio 1:10, a polymer containing chlorine was obtained. This consisted mainly of polyethylene oxide chlorohydrate. By fractional precipitation two solid polymers were separated with degrees of polymerization of approximately 23 and 100 (i.e., 23 and 100 monomeric groups per molecule).<sup>18</sup>

Polymerization of alkylene oxides is carried out commercially by passing the

<sup>16</sup> H. Staudinger, "Hochmolekularen Organischen Verbindungen," Verlag Julius Springer, Berlin, 1932, 257 et seq.

<sup>17</sup> H. Hibbert and S. Z. Perry, *Can. J. Research*, 1933, 8, 102; *Brit. Chem. Abs. A*, 1933, 373. A hypothesis of the formation of sugars and polysaccharides in plants based on the theory of the polymerization of ethylene oxide is given by H. Hibbert, *Can. J. Research*, 1933, 8, 103; *Chem. Abs.*, 1933, 27, 1866.

<sup>18</sup> H. Staudinger, "Hochmolekularen Organischen Verbindungen," Julius Springer, Berlin, 1932, 300. See also, A. Wirth, *Ann.*, 1863, 69, 331.

vapor at 40-60°C. over alkaline catalysts, such as caustic potash or caustic soda.<sup>19</sup> The degree of polymerization may be increased by employing higher temperatures, e.g., 120°C.<sup>20</sup> Ethylene oxide, for example, conducted over caustic soda forms a waxy mass. When anhydrous sodium bisulphate is used, dioxane is the chief product. Other procedures involve dissolving the oxide in an inert solvent,<sup>21</sup> e.g., carbon tetrachloride, benzene, or ethyl acetate, or in polyethylene glycol containing the alkaline catalyst,<sup>22</sup> and heating under pressure.

These viscous or solid polymers are employed as dispersing agents: a dispersion of montan wax with carnauba wax and castor oil may serve for floor polish and a dispersion with green earth (a ferrous silicate) and fuchsin is added to lime paints.<sup>23</sup> Other uses are as fillers for wood, as pastes, or for solutions or emulsions with which waxes, resin, or cellulose derivatives may be incorporated.<sup>24</sup> The polymers also find application in the manufacture of plastic molding compositions in which they serve as softeners,<sup>25</sup> in the preparation of colored pigments and lakes,<sup>26</sup> and as assistants in dyeing or stripping of dyes from textile fabrics.<sup>27</sup>

An agent for removing paint, varnish, and other coatings by pickling is made from a wax-like polymerization product (m.p. 50°C.) of ethylene oxide, xylene, butyl acetate, dichloroethylene and benzene.<sup>28</sup> The elasticity of such materials as collodion, wool, benzylcellulose, celluloid, leather, phenol-aldehyde condensation products or wood is increased by inclusion of alkylene oxide polymers.<sup>29</sup> Solutions of ethylene oxide polymer and collodion cotton or benzylcellulose in a mixture of benzene, toluene, butyl acetate and ethyl alcohol have been recommended as lacquers.<sup>30</sup> Waxes to be used as polishing compositions are obtained by the treatment of ethylene, propylene, or trimethylene oxide with natural or synthetic waxes or with paraffin, the materials being heated together at 120°-180°C. for several hours.<sup>31</sup>

By treating albumin with ethylene oxide, or other alkylene oxides, syrupy hygroscopic substances are formed which are soluble in water and are precipitated therefrom by tannin and picric acid. These condensation products are therapeutic agents.<sup>32</sup> Shellac and ethylene oxide, at 150°C., form resinous products which may be used in varnishes.<sup>33</sup> For example, 300 parts of shellac (acid value of 55) are treated with 90 parts of the oxide to give 350 parts of a viscous, dark colored resin. Similarly, colophony, ester gum or resins from phthalic anhydride and glycerol may be combined with ethylene oxide.

Esterification or etherization of non-carbohydrate organic compounds (containing hydroxyl or carboxyl groups) with polyethylene glycols or their monoethers or esters having at least four (C<sub>2</sub>H<sub>4</sub>O) groups yields wetting, foaming, or cleansing

agents.<sup>34</sup> Alcohols containing between 8 and 18 carbon atoms, particularly those from the catalytic reduction of vegetable oils and fats, fatty acids, or the hydrolysis of sperm oil, are especially applicable as the non-carbohydrate material. According to Oda,<sup>35</sup> ethylene glycol reacts with vegetable oils to furnish bodies which are soluble in ethyl alcohol. Distillation of the product from glycol and olive oil at 200°C. gives a residue which can be sulphonated to an emulsifying agent. A drying oil is obtained from glycol and linseed oil.

Glycidol,  $\text{O} \begin{array}{c} \text{CHCH}_2\text{OH} \\ | \\ \text{CH}_2 \end{array}$  heated for 42 hours at 100°C., yields a condensation product whose composition is regarded as<sup>36</sup>

At higher temperatures, substances having the same empirical formula but greater molecular weights are obtained. Polyglycidols may be prepared by polymerization of glycidol at low temperatures with the aid of condensing agents,<sup>37</sup> e.g., by treatment with stannic chloride at -25°C. Solid calcium chloride caused the rapid polymerization of glycidol (prepared from glycerol monochlorohydrin) to a water-soluble red tar. The reaction was highly exothermic.<sup>38</sup> Distillation of glycidol acetate, which had stood for 5 days at 135-140°C. or for several weeks at 12-13°C., gave the dimeric glycidol acetate (which slowly polymerized further), incompletely acetylated glycerols, monoacetin, triacetin, and polymers of glycidol acetate.<sup>39</sup>

#### POLYGLYCEROLS

In the distillation of crude glycerol, residues or foots are obtained which contain not only glycerol but also polymerized glycerol, aldehyde resins and other decomposition products together with salts. It has been stated that the residues can be dissolved in water, acidified, treated with lime, filtered, evaporated and redistilled in order to recover some of the glycerol.<sup>40</sup>

The dehydration of glycerol may be considered to take place either intermolecularly or intramolecularly. The first reaction, in which the elimination of water takes place between molecules, yields an ether type of linkage

When one molecule of water is eliminated (i.e.,  $y=1$ ) diglycerols are formed

When two molecules of water are lost between three molecules of glycerol, triglycerols result

In the presence of iron, or iron salts, intramolecular loss of water occurs with the formation of acrolein.<sup>41</sup>

<sup>41</sup> See Chapter 23.

Von Lourenço<sup>44</sup> prepared diglycerol by heating glycerol under reflux in the presence of hydrogen chloride for 12-15 hours at 100°C. The compound had a boiling point of 220-230°C. at 22 mm.<sup>45</sup> Triglycerol was also obtained under these conditions. Hibbert<sup>46</sup> used 0.05 per cent of iodine as a catalyst and heated the glycerol to 210°C. for 2 hours. On distillation there resulted an 85 per cent yield of water-white, viscous, hygroscopic liquid having a boiling point at 30 mm. of 257-260°C. The diglycerol was soluble in water but insoluble in ether. Moreover glycerol can be heated alone to temperatures of 200-275°C. to yield polyglycerols, especially if an inert gas is led through the solution to eliminate water as quickly as it is formed.<sup>47</sup> According to Lewis,<sup>48</sup> diglycerol occurs to the extent of about 2 per cent in ordinary glycerol and larger amounts are present in the glycerol which is prepared under high pressure in autoclaves.

Rayner<sup>49</sup> concluded that the conversion of glycerol into distillable polymerization products gives rise to substances of 2 types; the first consists of products obtained by intermolecular condensation of the diglycerol type

whereas the second is of the glycidic type in which intramolecular condensation occurs

By assuming the presence of these two types of derivatives the discrepant results of the properties of distillable polymerization products made by various investigators can be explained. By heating glycerol for 12 hours at 270-280°C. and separating the fraction boiling at 210-250°C. at 3 mm., a product is obtained which has a hydroxyl value of 34 per cent and a viscosity 5 times that of glycerol. Similar heating for a longer time and distillation of a fraction boiling at 260-265° at 10 mm. yielded a derivative which had a hydroxyl value of 38 per cent and a viscosity 13 times that of glycerol. From these results it appears that the first distillate contained glycidic, which possess a low viscosity.

The action of fused sodium acetate on 95 per cent glycerol followed by treatment with acetic anhydride and fractionation gives rise to the following derivatives: diglycerol tetra-acetate, triglycerol penta-acetate, tetraglycerol hexa-acetate, pentaglycerol hepta-acetate, hexaglycerol octa-acetate and heptaglycerol nona-acetate.<sup>48</sup> By continuing the condensation a crystalline acetin is obtained which appears to be the same as the diacetin of the homologous diglyceric alcohol from dichlorohydrin which was reported by Fauconnier and Sanson.<sup>49</sup>

Other catalysts include zinc chloride,<sup>50</sup> tantalum, thorium and magnesium oxides<sup>51</sup> together with sodium or potassium silicates as accelerators.<sup>52</sup> Sodium acetate can

also be used in the presence of inert gases such as carbon dioxide, nitrogen, hydrogen or water gas. Essentially diglycerol is formed under these conditions.<sup>54</sup> The use of mercuric chloride, mercury sulphate, cuprous chloride or ferric chloride in concentrations of 0.1-0.5 per cent with glycerol at temperatures between 250-275°C. yields a highly viscous reaction mixture. If the condensation is carried out in a stream of inert gas, di- and triglycerols are not formed but rather a transparent, brown-yellow colored, viscous liquid which is soluble in water and alcohol and has a flash point above 270°C. The material is said to be useful as a lubricant especially in contact with compressed oxygen inasmuch as it is "explosive-proof."<sup>54</sup>

Ushakov and Obriadina<sup>55</sup> tested the efficacy of various catalysts on the resinification of glycerol and determined that mercurous sulphate, aluminum sulphate and titanium sulphate were effective. Mercurous chloride, mercurous nitrate and mercuric nitrate were ineffective. Maximum yields of resin were obtained by using 4 per cent catalyst and heating for 10-14 hours. Upon vacuum-desiccation a dark brown resin resulted which was soluble in water, alcohol, alcoholic benzene and partially soluble in acetone. Further heating caused the resin to become infusible and insoluble. A baked film was glossy, flexible, insoluble in water and acetone and unaffected by dilute acids and alkalis. If the resin is dissolved in water and steam-distilled, the resulting product is insoluble in hot and cold water but soluble in alcohol and in aqueous alkaline solutions. Later experiments on the polymerization of glycerol indicate that a gelatinous or rubbery product can be prepared.<sup>56</sup>

#### POLYANHYDRIDES

Polymerization of the anhydrides of dibasic acids was observed by Hollemann and Voerman.<sup>57</sup> In attempting to measure the rate of reaction of such anhydrides with water, they observed that only those of succinic and glutaric acids gave satisfactory constants. Accurate measurements were not obtained with higher anhydrides (e.g., adipic, pimelic, suberic, azelaic, or sebacic) owing to their sparing solubility in water and polymolecular state. The latter condition was indicated also by boiling point determinations in acetone. Farmer and Kracovsky,<sup>58</sup> however, prepared adipic anhydride from the acid and acetic anhydride and considered it unimolecular.

Later Hill<sup>59</sup> made both a monomeric and a polymeric form of adipic anhydride. The former is a ring compound,

and the latter a linear polymer of the type,

which is broken down by heat *in vacuo*, forming the cyclic monomer. Investigations have been extended also to sebacic  $\alpha$ -anhydride, which is regarded as a chain-

<sup>59</sup> J. W. Hill, *J.A.C.S.*, 1930, 52, 4110.

like polymer, formed by the reaction between acetyl chloride or acetic anhydride and sebacic acid.<sup>60</sup> On heating this  $\alpha$ -anhydride to 200°C. in a molecular still<sup>61</sup> it is transformed into a polyanhydride of much higher molecular weight ( $\omega$ -anhydride) and a crystalline distillate ( $\beta$ -anhydride). The latter was shown to be a 22-membered cyclic dimer. At its melting point (68°C.),  $\beta$ -anhydride reverts to a higher polymer,  $\gamma$ -anhydride. At 130°C.  $\omega$ -anhydride is soft enough to be drawn into continuous filaments. These could be cold drawn and the resulting fibers were lustrous and very strong. On standing for a few days, however, they became fragile and brittle.

$\alpha$ -Anhydrides of dibasic acids, containing 7 to 18 carbon atoms, were prepared by the action of acetic anhydride on the corresponding acids.<sup>62</sup> The melting points of the various products are given in Table 50.

TABLE 50.—Melting Points of  $\alpha$ -Anhydrides.

$\alpha$ -Anhydride	Empirical Formula	Melting Point, °C.
Pimelic	$C_7H_{10}O_3$	53-55
Suberic	$C_8H_{12}O_3$	65-66
Azelaic	$C_9H_{14}O_3$	53-53.5
Undecanedioic	$C_{11}H_{18}O_3$	69-70
Dodecanedioic	$C_{12}H_{20}O_3$	86-87
Brassylic	$C_{13}H_{22}O_3$	76-78
Tetradecanedioic	$C_{14}H_{24}O_3$	89-91
Octadecanedioic	$C_{18}H_{32}O_3$	94-95

In all instances  $\alpha$ -anhydrides were linear polymers and when heated in a molecular still yielded  $\omega$ - and  $\beta$ -anhydrides,<sup>63</sup> and the latter in turn, either on further heating or on standing, changed to  $\gamma$ -anhydrides. These transformations can be summarized by the following scheme:

The physical properties of cyclic ( $\beta$ -) anhydrides, obtained by depolymerization of  $\alpha$ -anhydrides, are given in Table 51.

TABLE 51.—Physical Properties of Cyclic Anhydrides.

Acid	Structural Unit of Anhydride	Product of Depolymerization and Size of Ring	Stability	Melting Point °C.
Adipic	$-\text{OC}(\text{CH}_2)_4\text{CO}-\text{O}-$	Monomer 7	Unstable	20
Pimelic	$-\text{OC}(\text{CH}_2)_5\text{CO}-\text{O}-$	Monomer 8	Extremely unstable	Liquid
Suberic	$-\text{OC}(\text{CH}_2)_6\text{CO}-\text{O}-$	Dimer 18	Stable up to m.p.	56-57
Azelaic	$-\text{OC}(\text{CH}_2)_7\text{CO}-\text{O}-$	Monomer 10	Extremely unstable	Liquid
Sebacic	$-\text{OC}(\text{CH}_2)_8\text{CO}-\text{O}-$	Dimer 22	Stable up to m.p.	68
Undecanedioic	$-\text{OC}(\text{CH}_2)_9\text{CO}-\text{O}-$	Monomer 12	Extremely unstable	Liquid
Dodecanedioic	$-\text{OC}(\text{CH}_2)_{10}\text{CO}-\text{O}-$	Dimer 26	Stable up to m.p.	76-78
Brassylic	$-\text{OC}(\text{CH}_2)_{11}\text{CO}-\text{O}-$	Monomer 14	Unstable	Liquid
Tetradecanedioic	$-\text{OC}(\text{CH}_2)_{12}\text{CO}-\text{O}-$	Monomer 15	Unstable	Liquid

<sup>62</sup> J. W. Hill and W. H. Carothers, *J.A.C.S.*, 1932, 55, 5022.

<sup>63</sup> The stereochemistry and mechanism in the formation and stability of large rings is discussed by W. H. Carothers and J. W. Hill, *J.A.C.S.*, 1933, 55, 5043.

It is interesting to note that cyclic anhydrides, particularly those containing 10 or more carbon atoms, possess a spicy or musk-like odor.<sup>64</sup> This is in accordance with the observations of Ruzicka<sup>65</sup> that the essential principles of musk and civet are compounds containing the C=O grouping (macrocyclic ketones). Spontaneous polymerization of cyclic anhydrides on standing, however, is accompanied by a disappearance of their odor.

That  $\alpha$ -anhydrides are linear polymers is indicated by their reaction with aniline to form monoanilide, dianilide, and free acid. With the polyanhydride of adipic acid, for example, this breaking of the molecule may be represented by:<sup>66</sup>

Similar reactions take place with ammonia, diethylamine, and phenol. A general equation for such reactions, which does not consider the end groups, is:

The monomeric anhydride, on the other hand, furnishes only the monoanilide.

In the presence of aluminum chloride, polyanhydrides react with benzene to give dibenzoyl alkane,  $\omega$ -benzoyl fatty acid, and dibasic acid.<sup>67</sup>

In the case of polyesters derived from hexadecamethylene dicarboxylic acid and trimethylene glycol, continuous filaments are made by drawing out the molten ester or by dissolving the ester in chloroform and extruding the solution through a rayon spinneret.<sup>68</sup> The molten ester may be extruded also. In this manner filaments are made which are 0.001 inch in diameter, melt at 74-75°C., and are

<sup>64</sup> J. W. Hill and W. H. Carothers, *J.A.C.S.*, 1933, 55, 5039.

<sup>67</sup> J. W. Hill, *J.A.C.S.*, 1933, 54, 4105.

<sup>68</sup> W. H. Carothers and J. W. Hill, *J.A.C.S.*, 1933, 54, 1579.

opaque and devoid of luster. If, however, tension is applied during spinning then the filaments are transparent and highly lustrous, while their strength and pliability are greatly increased. Reference is made in Chapter 4 to the differences in the x-ray patterns of these types of fibers.

Fibers resembling the above were obtained from the polyesters of  $\omega$ -hydroxydecanoic acid,  $\omega$ -hydroxypentadecanoic acid, ethylene glycol and sebacic acid, trimethylene glycol and adipic acid, and ethylene glycol and succinic acid. Those from polyanhydrides (e.g., sebacic acid anhydride) have a specially high strength, pliability, and luster, though they gradually disintegrate owing to hydrolytic degradation.

Dibasic acids, derived from cyclic or aromatic hydrocarbons, may be the source of polyanhydrides. For example, trans-1,2-dimethylcyclopropane-1,2-dicarboxylic acid is converted by treatment with acetyl chloride into a polymeric non-crystalline anhydride.<sup>66</sup> Also cis-p-hexahydroterephthalic acid reacts with acetic anhydride to give a polymeric cis-anhydride

which at 230°C. changes into the corresponding trans-polyanhydride.<sup>66</sup> Distillation of either polyanhydride of hexahydroterephthalic acid, under reduced pressure with rapid cooling, yields acetic anhydride vapor and the monomeric anhydride. The latter is very unstable and polymerizes when melted or warmed in benzene in the presence of a trace of sodium hydroxide.

#### POLYAMIDES AND MIXED POLYESTER-POLYAMIDES

Amino acids having four or five carbon atoms lose water on heating and yield the corresponding lactams. Thus,  $\gamma$ -aminobutyric acid<sup>70</sup> and  $\delta$ -aminovaleric acid<sup>71</sup> are converted to 5- and 6-membered cyclic lactams, respectively. Under similar conditions, higher amino acids give rise to polymerized compounds.  $\epsilon$ -Aminocaproic acid, for example, furnishes 20-30 per cent of the 7-membered cyclic lactam and 80-70 per cent of a non-distillable, polymerized material of approximately the same composition.<sup>72</sup>  $\xi$ -Aminoheptonic acid on heating undergoes intermolecular reactions resulting in the formation of products<sup>73</sup> which differ in their properties from the 8-membered lactam prepared by other methods.<sup>74</sup>

The mixture of polymer (polyamide) and lactam from  $\epsilon$ -aminocaproic acid is separated by distillation or by extraction with alcohol.<sup>75</sup> The former is a hard gray wax, insoluble in most organic solvents, but can be recrystallized from formamide. Its molecular weight (in phenol) is about 800-1200. It can be quantitatively hydrolyzed to  $\epsilon$ -aminocaproic acid by boiling concentrated hydrochloric acid. Partial hydrolysis yields polyaminocaproylaminocaproic acid. The structure assigned to the polyamide is

Carothers and Hill<sup>76</sup> have pointed out the analogy between this type of polymer and the polyesters obtained by self-esterification of higher hydroxyacids or from the action of glycols on dibasic acids. In the first instance the binding agent be-

<sup>73</sup> W. H. Carothers and G. J. Berchet, *J.A.C.S.*, 1930, 52, 5289.

<sup>74</sup> W. H. Carothers and J. W. Hill, *J.A.C.S.*, 1933, 54, 1546.

tween the units is  $\text{—O—}$ , and in the latter is  $\text{—NH—}$ . The polyamides are, in general, harder, tougher, less easily fusible, and much less soluble than polyesters. Similar to the changes observed with polyanhydrides, the polyamide when heated for 48 hours at  $200^{\circ}\text{C}$ . in a molecular still was transformed to a volatile cyclic lactam which is a harder and tougher material and in thin sections is plastic and flexible.

The same investigators attempted the preparation of mixed polyester-polyamides. The polyesters previously noted are not entirely satisfactory for the manufacture of synthetic silk owing to their low melting points and considerable solubility in organic solvents. The polyamide, on the other hand, is too infusible and insoluble for use in making fibers. The mixed polyester-polyamides were intended as a compromise between these two extremes.

Such compounds were obtained by heating mixtures of trimethylene glycol, hexadecamethylene dicarboxylic acid, and  $\epsilon$ -aminocaproic acid for three hours at  $200\text{--}220^{\circ}\text{C}$ . The glycol and acid were present in equivalent proportions, and amounts of amino acid varied from 1 to 5 mols per mol of the dibasic acid. Heating was continued for 5 hours more at 1 mm. pressure at  $250\text{--}260^{\circ}\text{C}$ . and the viscous residue then was transferred to a molecular still and heated for three days at  $200^{\circ}\text{C}$ . As the proportion of amino acid was increased the polymers increased in brittleness, hardness, transparency and melting point, but their solubility diminished. Polymers containing the higher proportions of amino acids were insoluble in ethyl acetate: with less of the acid the compounds dissolved in this solvent. Since the polyamide itself is insoluble in hot ethyl acetate, the mixed polyester-polyamides cannot have been merely physical mixtures. These mixed compounds could be drawn into strong, pliable transparent fibers which were superior to those from the polyester alone.

Abderhalden and Reich<sup>77</sup> found that  $\beta$ -alanine methyl ester, when kept for a few days, yielded a white amorphous solid, insoluble in ether, and decomposing at  $310^{\circ}\text{C}$ . Molecular weight determinations indicated a 5-fold polymerization. In the preparation of hexamethylenimine by treating 6-bromo-*n*-hexylamine,  $\text{NH}_2(\text{CH}_2)_6\text{Br}$ , with alkali and distilling with steam, an amorphous residue of the composition  $(\text{C}_6\text{H}_{12}\text{N})_n$  is obtained.<sup>78</sup>

#### LACTONE FORMATION

Lactone formation is of importance in the chemistry of resins, an example of a naturally occurring product of this type being shellac. Lactones, or inner esters, are obtained by the elimination of water between a hydroxyl group and a carboxyl group, both of which are in the same molecule. With  $\gamma$ - or  $\delta$ -hydroxyacids the reaction can be represented by:

Closely related to this type of compounds are lactides, or cyclic esters, resulting from the elimination of water between hydroxyl and carboxyl groups in two molecules of an  $\alpha$ -hydroxy acid. For lactic acid this can be illustrated as follows:

When the carboxyl and hydroxyl groups are widely separated, lactone formation is accompanied by the development of other products. Thus,  $\epsilon$ -hydroxyacids give

<sup>77</sup> E. Abderhalden and F. Reich, *Z. physiol. Chem.*, 1928, 178, 169; *Brit. Chem. Abs. A*, 1929, 52.

<sup>78</sup> J. von Braun and O. Goll, *Ber.*, 1927, 60, 1833; *Chem. Abs.*, 1927, 21, 3156.

lactones and polyesters (polylactones)<sup>79</sup> and  $\omega$ -hydroxyacids yield almost exclusively polyesters.<sup>80</sup> Lactones of high molecular weight can be made by oxidation of the corresponding ketone.<sup>81</sup> The slow addition of sodium persulphate (in sulphuric acid) to a cold solution of civetone in benzene resulted in an emulsion containing a resin, together with a small amount of a petroleum-ether-soluble lactone.<sup>82</sup>

Many lactones, particularly six-membered cyclic esters, are known to polymerize with ease, and depolymerize (reversible polymerization) on heating. Carothers, Dorough, and Van Natta<sup>83</sup> have drawn attention to such instances.

$\delta$ -Valerolactone,  $\text{CH}_2 \begin{array}{c} \text{CH}_2\text{CH}_2 \\ \diagup \quad \diagdown \\ \text{CH}_2 \end{array} \begin{array}{c} \text{CO} \\ \diagdown \quad \diagup \\ \text{O} \end{array}$ , which is initially a mobile oil, gradually thick-

ens, and finally solidifies to a crystalline mass, which proves to be a 5- to 7-fold polymer.<sup>84</sup> The partial decomposition of this lactone as it approaches its boiling point has been attributed to the formation of a polymer.<sup>85</sup> Drew and Haworth<sup>86</sup> observed the polymerization of the crystalline lactone of 2,3,4-trimethyl-l-arabonic acid,

in the presence of a trace of hydrogen chloride and its depolymerization on heating. Bischoff<sup>87</sup> noted the reversible polymerization of ethylene oxalate,  $\text{CH}_2 \begin{array}{c} \text{O} \\ \diagup \quad \diagdown \\ \text{CO} \end{array} \begin{array}{c} \text{CH}_2 \\ \diagdown \quad \diagup \\ \text{O} \end{array} \text{CO}$ , prepared from ethylene glycol and monoethyl oxalate.

Extending these observations on the reversible polymerization of 6-membered rings, Carothers and his co-workers found that substituting groups generally reduced the tendency for such molecules to polymerize. Thus,  $\delta$ -valerolactone was completely polymerized to a waxy solid on standing for 29 days at room temperature.  $\alpha$ -n-Propyl- $\delta$ -valerolactone remained unchanged for 1 year at room temperature or at 80°C. for one month. Under the latter conditions addition of a trace of potassium carbonate or zinc chloride caused the lactone to become viscous and its apparent molecular weight to rise to 1100-1200. On the other hand, the lactide of  $\alpha$ -hydroxypropionic acid (lactic acid) was transformed in two hours at 250-275°C. to a resinous mass with a molecular weight of about 3000. In the presence of potassium carbonate polymerization took place at 140-150°C.

The effect of substituting groups is shown also by the work of Palomaa and Toukola.<sup>88</sup> They report that  $\gamma$ -hydroxypropoxyacetic acid, at 200-220°C. and

0.1-1 mm. pressure, passes into the corresponding lactone which is not polymerized.

Furthermore, this lactone is hydrolyzed (in acid solution) only about 1/90 as

fast as the homologous compound,  $\begin{array}{c} \text{CH}_2\text{CH}_2 \\ \diagup \quad \diagdown \\ \text{O} \quad \text{O} \\ \diagdown \quad \diagup \\ \text{CH}_2\text{CO} \end{array}$ , which has one less  $\text{CH}_2$  group.

Lycan and Adams<sup>20</sup> synthesized intermolecular esters by heating  $\omega$ -hydroxyacids, the molecular weights of the esters varying from 1000 to 9000. Carothers and Van Natta<sup>21</sup> similarly prepared polyesters (molecular weights ranging from 780 to 25,000) from  $\omega$ -hydroxydecanoic acid.<sup>21</sup> Strong, oriented fibers were obtained from polyesters of molecular weights greater than 9330. Maximum tensile strength, 13.1 kg. per sq.mm. (ca. 18,500 lbs. per sq. in.), was exhibited by fibers with a molecular weight of 16,900.

Carothers<sup>22</sup> further suggests that the polymers are linear polyesters having a chain structure of the type

It seems probable that the first step in the polymerization of cyclic esters (lactones) involves the intervention of a trace of the corresponding hydroxy acid. This reacts with the lactone to give the dimeric acid. The latter in turn yields a trimeric acid, and reaction continues until all the lactone is exhausted or the chains become too long for further reaction. In the case of  $\delta$ -valerolactone, the first stage in polymerization may be represented by:

Crude  $\epsilon$ -hydroxycaproic acid (containing some of the corresponding lactone) on being heated to 150-210°C. gave  $\epsilon$ -caprolactone, and a small proportion (about 1 per cent) of the dimeric, cyclic self-ester of  $\epsilon$ -hydroxycaproic acid.<sup>23</sup> When kept in a sealed tube for 12 hours at 150°C., the lactone slowly became more viscous and, on cooling, solidified to a solid mass. A trace of potassium carbonate reduced the heating time to about 5 hours. The lactone, dimer, and polyester were derivatives of  $\epsilon$ -hydroxycaproic acid and no shift of the hydroxyl oxygen was involved in their formation. Coucoulesco<sup>24</sup> reports that a trimethyl hydroxycaproic acid,  $\text{CH}_3\text{CH}(\text{CH}_3)\text{CHOHCH}_2\text{C}(\text{CH}_3)_2\text{COOH}$ , when distilled from dilute sulphuric yielded a white amorphous resin, possibly the polymerized lactone,

An important contribution to the chemistry of hydroxy acids is that of Chuit

and Hausser,<sup>95</sup> who synthesized and studied the properties of hydroxy fatty acids containing 8-21 carbon atoms. Several derivatives of these acids were isolated from waxes extracted from conifers.

Resinification of mandelic acid was noted by Ipatiev and Rasuvajev<sup>96</sup> when they attempted to hydrogenate this acid in the presence of a nickel catalyst. Brittle resins, apparently lactides, result from the thermal decomposition of 4-carboxy-2,6-dimethylmandelic acid<sup>97</sup> and of benzilic acid.<sup>98</sup>

### LACTIC ACID

This acid is of interest in connection with synthetic resins not only because of its yielding lactides when heated but also because it may be employed in resinification studies.

Commercial lactic acid contains about 75 per cent of acid, whose constitutional formula is  $\text{CH}_3\text{CHOHCOOH}$ , together with about 8 per cent of its anhydrides whose formulas can be represented by

The former is a monoanhydride and the latter a dianhydride or lactide. Hydrolysis of anhydride and lactide occurs with formation of lactic acid when either substance is heated with water or acid or alkaline aqueous solutions. A method for the analysis of mixtures of lactic acid and its anhydrides is described by Thurmond and Edgar.<sup>99</sup>

Wislicenus<sup>100</sup> reported that the anhydride obtained by heating lactic acid in a current of air at 130°C. was a light-yellow, amorphous body, slightly soluble in water and very soluble in alcohol or ether. The lactide has been described as a white, crystalline solid, very slightly soluble in alcohol or ether,<sup>101</sup> and is formed at a higher temperature than that required for the anhydride, namely 200°C.

The reaction of lactic acid, as well as its acid or basic sodium, calcium and barium salts, with water at 200-450°C. under pressure was investigated by Fischer, Schrader, and Wolter.<sup>102</sup> The acid yielded acetaldehyde, together with acetone and resins, and very little alcohol was formed. In addition, considerable quantities of carbon monoxide, hydrogen, unsaturated hydrocarbons, methane, and ethane were produced. From the salts, however, 15-20 per cent of alcohol was obtained, except from a basic sodium lactate which gave only a trace of alcohol. Krauskopf and Carter<sup>103</sup> noted that barium lactate could be crystallized from a solution containing barium hydroxide, whereas a neutral solution or one containing free lactic acid could be evaporated to a thick syrup and in some instances to a glass-like solid without the formation of crystals. The amorphous material was shown to have the same composition as the crystalline lactate. Lactates of other metals, especially the more electropositive ones, behaved similarly; for example, crystal-

line lactates of the alkali metals could not be obtained. The lactide anhydride was shown to inhibit crystallization, its probable mode of action being that of a protective colloid.

**Resins from Lactic Acid.** A resin is obtained by refluxing 90 per cent lactic acid for several hours and then removing the volatile portion by distillation.<sup>106</sup> The product is light yellow in color, melts at 30-35°C., is soluble in acetone, alcohol, and other organic solvents, and is miscible with cellulose acetate. Lacquers in which this resin is incorporated yield clear, hard films which possess the property of sticking to various surfaces. The lactic acid resin (together with cellulose acetate) has been considered also in the manufacture of laminated glass,<sup>105</sup> and as an adhesive for making composite sheets from thin films of cellulose derivatives by heat and pressure.<sup>106</sup>

Zimmermann<sup>107</sup> heats lactic acid *in vacuo*, raising the temperature slowly from 100 to 200°C., and condenses the product with formaldehyde or paraldehyde. An odorless, non-inflammable, resinous product, soluble in chloroform or glacial acetic acid, and slightly soluble in benzene, is thus obtained. Its color varies from pale yellow to almost black, according to the purity of the lactic acid employed.

#### RELATED PRODUCTS

After heating glycolic acid very gradually to 150°C., maintaining it at this temperature for several hours, and then cooling, a hard compact mass is obtained.<sup>108</sup> This substance possesses unusual adhesive properties, a strength of 1 ton per square inch being obtained when it was applied to very smooth (but not optically polished) surfaces. In this respect "overheated" glycolic acid compares favorably with many other adhesives such as marine glue, high-grade rosin, ester gum, and Bakelite "A." In the preparation of resins from formaldehyde and phenol with sodium hydroxide solution as a catalyst, the addition of glycerol esters of lactic acid yields a clearer product.<sup>109</sup>

#### ARTIFICIAL SHELLAC

The problem of the constitution of natural shellac thus far is unsolved. Harries and Nagel,<sup>110</sup> however, isolated some degradation products of the natural resin and from an examination of these concluded that shellac is a mixture of substances obtained by the lactide condensation of various hydroxy-carboxylic acids. Two acids in particular were isolated: aleuritic acid, whose formula is probably<sup>111</sup>

and shellolic acid (shellenedioldicarboxylic acid) for which the formula

<sup>112</sup> A. Tschirch and A. Farmer (*Arch. Pharm.*, 1890, 237, 39; *J.C.S.*, 1890, 76 (1), 446) suggest that aleuritic acid is a dihydroxyundecic acid.

is suggested. Heating mixtures of these two acids (in varying molecular proportions) under reduced pressure at 150-160°C. yielded yellow, liquid lactides, which on cooling became yellow resinous masses. Harder and more infusible resins were produced by using temperatures above 200°C. A possible formula for one of the simpler components of shellac is

Another structure<sup>112</sup> suggested for lac resin is

which is based on the assumption that pure lac resin consists of 30 per cent of aleuritic acid, 10 per cent shellolic acid and 60 per cent unknown hydroxy acids similar to shellolic acid. In the above formula shellolic acid is considered to be a reduced dihydroxyisopropyl naphthalene dicarboxylic acid.

<sup>112</sup> W. Nagel and E. Baumann, *Wiss. Veröff. Siemens-Konz.*, 1923, 11, 99; *Brit. Chem. Abs. B*, 1923, 30.

Bhattacharya<sup>112</sup> isolated a shellolic acid which differed in many respects from that described by Nagel. A comparison of the two acids is given in Table 52.

TABLE 52.—*Characteristics of Shellolic Acid.*

	Nagel 200-201°C. (decomp.) Non-hygroscopic	Bhattacharya 90-91°C. Hygroscopic
Melting Point		
Mol. wt. (from sap. val.)	297	298
Zn content of Zn salt	17.85%	17.6%
Analysis by combustion	$C_{11}H_{20}O_6$	$C_{11}H_{20}O_6-H_2O$
$[\alpha]_D^{25}$	32.6°	30°
M. p. of Methyl Ester	149°C.	Viscous liquid
M. p. of Hydrazide	243-244°C.	131°C.
M. p. of p-Bromophenacyl ester	...	175-176°C.

The formula  $C_{11}H_{20}O_6-H_2O$  indicates that combustion values were in agreement with those for the lactone  $C_{11}H_{20}O_6$ . Lactone formation was verified by the differences in acid and saponification values. According to Bhattacharya, shellolic acid possesses a condensed three-benzene-ring structure in which the orientation of the carboxyl and hydroxyl groups has not yet been determined.

Although shellac is insoluble in aqueous solutions of alkali bicarbonates it does dissolve in solutions of alkali carbonates, thus possibly indicating the presence of phenolic groups.<sup>114</sup> Furthermore, molecular weight determinations and analyses of the heavy-metal salts of shellac lead to the conclusion that the resin molecules are dibasic acids. Gardner and Whitmore<sup>115</sup> report that the best solvents for shellac are alcohols, ketones, and organic acids. Since many substances are often more soluble in those solvents related to them structurally,<sup>116</sup> the indications are that hydroxyl, carbonyl, and carboxyl groups are present in shellac. Because of the insolubility of shellac in ethylene glycol and glycerol, it is believed also that the hydroxyl groups in aleuritic acid are involved in some other grouping, e.g., that of a lactide.

In synthesizing shellac-like resins, lactic, glyceric, dihydroxy-, trihydroxy-, or tetrahydroxy-stearic acids, or the oxidation products from linseed oil acids may be substituted for aleuritic acid. As the second component, in place of shellolic acid, cyclohexanocarboxylic acids, tetrahydronaphthoic acid, or their hydroxy derivatives may be employed. On heating mixtures of these acids, resins resembling shellac are obtained.<sup>117</sup> In a similar manner copals and polyhydroxy fatty acids give shellac substitutes.<sup>118</sup>

Scheiber and Noack<sup>119</sup> found that resin formation generally resulted from the interaction of aliphatic oxycarboxylic acids (e.g., those from the moderate oxidation of unsaturated fatty acids) with hydroaromatic oxycarboxylic acids (such as oxidized resin oil acids). To illustrate, 100 parts of oxidized soluble Manila copal, 100 parts of oxidized rosin, and 25 parts of castor oil acids are heated gradually to 200°C. The resinous product is soluble in alcohol, alkali carbonate and borax solutions, and insoluble in hydrocarbons and fatty oils. Variations of this procedure consist in the substitution of one of the components by chlorinated derivatives<sup>120</sup> (for example, a mixture of trihydroxystearic acid and chlorinated abietic acid) or in the chlorination

of a mixture of unsaturated fatty acids and resinolic acids<sup>121</sup> and effecting condensation by heating.<sup>122</sup> Anhydrous metallic chlorides (zinc or aluminum chloride) serve as catalysts

The formation of synthetic resins as described above apparently entails a lactide condensation in each instance and offers a close parallel with the case of natural shellac. Of a somewhat different nature is the production of resins by polymerization of benzyl and cinnamic alcohols by such agents as sulphuric or phosphoric acid, or phosphorus pentoxide. The reaction mixture is heated first to 130° and then to 180°C. An alternative procedure is to heat a mixture of phosphoric acid, an aromatic hydrocarbon, and formaldehyde, the latter two components forming an alcohol *in situ* which is then polymerized. Resins so obtained are soluble in organic solvents and may be employed in paints and varnishes.<sup>123</sup>

### VINYL ETHERS

Although vinyl alcohol,  $\text{CH}_2=\text{CHOH}$ , has not yet been isolated because of its instability, nevertheless a number of its derivatives are known and of these the vinyl ethers are of considerable importance owing to their tendency to polymerize. Vinyl ethyl ether,  $\text{CH}_2=\text{CHOC}_2\text{H}_5$ , was described first by Wislicenus<sup>124</sup> who made it by the action of sodium on chloroacetal.

Claisen's<sup>125</sup> method of preparation depends upon the removal of alcohol from diethyl acetal,  $\text{CH}_3\text{CH}(\text{OC}_2\text{H}_5)_2$ , by phosphorus pentoxide in the presence of quinoline. Vinyl and other unsaturated ethers may be obtained by passage of the vapors of aliphatic or aromatic acetals (with or without a diluent) over metals, such as silver, gold, or platinum, at temperatures of 200–350°C. Other metals, oxides, phosphates, or silicates may be added to the catalysts.<sup>126</sup>

Further procedures involve dissolving acetylene (or its homologues) under pressure in sulphuric acid at 0° to –15°C., using mercuric sulphate as a catalyst, and reacting the acid sulphate with alcohol.<sup>127</sup> Hydroxylated compounds, which do not contain groups sensitive to alkalies, are reported to combine with acetylene, at temperatures of 80–250°C. in strongly alkaline media.<sup>128</sup> In this way it is possible to prepare the ethyl vinyl ether of ethylene glycol (b.p. 126°C.) from the monoethyl ether of ethylene glycol, as well as the monovinyl ether of diethanolamine, and vinyl octyl ether.

<sup>121</sup> Resinolic acids are those acids occurring in natural resins: A. H. Allen, "Commercial Organic Analysis," P. Blakiston's Son & Co., Philadelphia, 1907, 2, 143. R. S. Ernst and Berndt<sup>120</sup> suggest treating aromatic hydroxy compounds with vinyl halides (particularly the chlorides) in the presence of bases and, optionally, of catalysts. Phenol, sodium hydroxide, water, and vinyl chloride, for example, when fused together at 180-200°C. gave an 80 per cent yield of vinyl phenyl ether. Reaction of vinyl monohalides with alcoholates or phenylates, in the presence of a solvent, or with mixtures of alcohols and oxides or hydroxides of alkali or alkaline earth metals, also furnishes vinyl ethers.<sup>120</sup> Ethylene or ethylidene dihalides may be employed in a similar manner. To illustrate, ethylene dichloride and sodium ethoxide form ethyl vinyl ether, while vinyl cyclohexyl ether (b.p. 147-148°C.) is obtained from cyclohexanol, sodium hydroxide, and ethylene dibromide.<sup>121</sup>

Unsaturated ethers of nuclear-methylated hydroxybenzyl alcohol have been prepared by Melamid<sup>122</sup> by treating the alcohols obtained from m- and p-cresol and formaldehyde with a caustic alkali solution (20 per cent) and an allyl halide. Oily compounds are derived which solidify by absorption of oxygen and consequently are applicable as drying oils. Similar products were obtained by employing anthracene oil in place of cresols,<sup>123</sup> the alkali-soluble constituents reacting to form ethers.

Chalmers<sup>124</sup> describes the conversion of alkyl  $\beta$ -bromoethyl ethers into vinyl derivatives by treatment with solid sodium hydroxide. The bromoethers are prepared by the action of phosphorus tribromide on the corresponding glycol monoethers and then distilled in the presence of the alkali. During distillation vinyl ethers and dialkylethers of diethylene glycol are formed simultaneously.

The physical constants for some vinyl ethers are given in Table 53.

TABLE 53.—Physical Constants of Vinyl Ethers.

Ether	Boiling Point, °C.	Density (D <sub>4</sub> <sup>20</sup> )	Refractive Index (n <sub>D</sub> <sup>20</sup> )
Vinyl methyl.....	12-14°	.....	.....
Vinyl ethyl.....	35.5°	0.7589	1.3856 (n <sub>D</sub> <sup>25</sup> )
Vinyl n-butyl.....	93.3°	0.7887	1.4026
Vinyl $\beta$ -chloroethyl ....	108.0°	1.044	1.4362
Vinyl phenyl.....	155.5°	0.9776	1.5226

Divinyl ether is prepared by the action of heated caustic alkali on  $\beta$ , $\beta'$ -dichloroethyl ether.<sup>125</sup> Best yields and smaller proportions of by-products (acetaldehyde, dioxane, ethylene oxide, and  $\beta$ -chloroethyl vinyl ether) are secured when the temperature is 200-250°C. and the alkali is stirred to prevent its surface from becoming coated with alkali chloride.<sup>126</sup> The ether boils at about 23°C.

Phenyl vinyl ether (b.p. 155-156°C.) is obtained by heating  $\beta$ -bromophenetole,  $\text{C}_6\text{H}_5\text{OCH}_2\text{CH}_2\text{Br}$ , with anhydrous potassium hydroxide.<sup>127</sup> Another method of

<sup>128</sup> A. Wohl and E. Berthold, *Ber.*, 1910, 43, 2175. The preparation of eugenyl vinyl ether and guaiacyl vinyl ether by analogous methods is described also.

preparing aromatic vinyl ethers consists in converting  $\beta$ -halogenated ethyl aromatic amines, such as

to the corresponding ethers, e.g.,

afterwards forming the quarternary salts by reaction with methyl iodide or sulphate, and decomposing the salt with alkali.<sup>120</sup> The last reaction, which apparently occurs only when R is an aromatic group, may be represented by:

Lauer and Spielman<sup>120</sup> suggest the following procedure: The phenol is transformed to the corresponding hydroxy ether, which is chlorinated with thionyl chloride, and hydrogen chloride then eliminated with potassium hydroxide.

Powell and Adams<sup>140</sup> report that thermal decomposition of phenyl vinyl ether (12 hours at 260-280°C.) leads to the formation of some phenol. Lauer and Spielman<sup>141</sup> found that this ether when heated for 3 hours at 295-300°C. gives only a small proportion of phenol, some acetaldehyde diphenyl acetal  $\text{CH}_3\text{CH}(\text{OC}_6\text{H}_5)_2$ , and a tarry residue. The acetal appeared to result from the interaction of phenol (formed by decomposition of the ether) and phenyl vinyl ether.

Hydroxyethyl vinyl ether is prepared by the action of sodium on bromoethylidene glycol and hydrolysis of the sodium derivative thus formed.<sup>142</sup>

The ether is a colorless oil, boiling at 140°C., soluble in water, ether, and benzene, but insoluble in ligroin. Traces of strong acids (sulphuric or hydrochloric) effect an instantaneous and almost explosive rearrangement of the ether to the cyclic acetal, ethyldene glycol.

<sup>120</sup> J. von Braun and G. Kirschbaum, *Ber.*, 1920, 53, 1399.

<sup>120</sup> W. M. Lauer and M. A. Spielman, *J.A.C.S.*, 1933, 55, 1572.

<sup>140</sup> S. G. Powell and R. Adams, *J.A.C.S.*, 1920, 42, 646.

<sup>141</sup> W. M. Lauer and M. A. Spielman, *loc. cit.*

<sup>142</sup> H. S. Hill and L. M. Pidgeon, *J.A.C.S.*, 1923, 50, 2718. *Cf.* J. Wislicenus, *Ann.*, 1878, 192, 112.

The benzoate of hydroxyethyl vinyl ether, however, does not undergo a similar transformation, indicating that the hydroxyl group plays a specific role in the reaction. Hydroxypropyl vinyl ether, prepared in a similar manner from bromoethylidene trimethylene glycol, exhibits analogous properties.<sup>144</sup>

$\alpha$ - and  $\beta$ -Unsaturated, substituted ethers<sup>144</sup> were produced by passing hydrogen chloride into a mixture of an aldehyde and an alcohol to secure the chloro ether. Bromination, followed by treatment with the Grignard reagent, resulted in  $\beta$ -bromo ethers. These yielded vinyl derivatives on distillation over potassium hydroxide. For example, from  $\alpha$ ,  $\beta$ -dibromoethyl ether was obtained  $\alpha$ -ethoxystyrene (b.p. 109-112°C. at 30 mm.).

The substituted vinyl ethers hydrolyze under the influence of a trace of acid to the corresponding acetone (in the above case acetophenone).

Halogenated vinyl ethers are made by the action of zinc on halogenated derivatives of ethyl ether.<sup>145</sup> The essential condition for this reaction appears to be that three halogen atoms must be attached to the  $\beta$ -carbon atom and one or more to the  $\alpha$ -carbon. To illustrate,  $\alpha$ -chloro- $\beta,\beta,\beta$ -tribromodiethyl ether and zinc yield  $\beta,\beta$ -dibromovinyl ether,

while  $\alpha,\beta,\beta,\beta$ -tetrachlorodiethyl ether gives  $\beta,\beta$ -dichlorovinyl ether,

On the other hand, addition of zinc to  $\alpha,\beta,\beta$ -trichloroethyl ether results in the evolution of hydrogen and formation of tarry masses, indicating the elimination of hydrogen chloride by zinc and decomposition of the dichlorovinyl ether formed. When this trichloroether and zinc react in the presence of a large proportion of alcohol, dichloroacetal is the main product.

**Polymerization of Vinyl Ethers.** Ethyl and n-butyl vinyl ethers were almost completely polymerized in 24 hours by 0.2 per cent of iodine, while the  $\beta$ -chloroethyl ether polymerized very slowly and the phenyl compound remained unchanged.<sup>146</sup> The colorless polymers were sticky pitch-like materials, mobile above 100°C., and slowly dissolved in chloroform or benzene. Molecular weight determinations, in the latter solvent, indicated 18-82 units per molecule. When a larger proportion of iodine (0.5 to 5 per cent) was employed, reaction was violent and black polymers, soluble in most of the common solvents (except alcohols), were formed. Methyl, ethyl, and n-butyl vinyl ethers were affected slowly by heat or ultraviolet light, and vigorously by a trace of volatile metallic halides such as stannic chloride or antimony pentachloride.

The rates of polymer formation, at 130°C., of some vinyl ethers are shown in Table 54.

TABLE 54.—Rates of Polymer Formation of Vinyl Ethers.

Ether	Time, Days.	Polymer formed, %.
Vinyl ethyl.....	60	46.5
Vinyl n-butyl.....	60	26.0
Vinyl $\beta$ -chloroethyl.....	3	100.0 (approx.)
Vinyl phenyl.....	90	1.6

<sup>142</sup> H. S. Hill, *J.A.C.S.*, 1923, 50, 2725.

<sup>144</sup> W. M. Lauer and M. A. Spielman, *J.A.C.S.*, 1931, 53, 1533.

<sup>145</sup> F. Neher and C. L. Fleece, *J.A.C.S.*, 1926, 48, 2416.

<sup>146</sup> W. Chalmers, *Can. J. Research*, 1932, 7, 472; *Brit. Chem. Abs. A*, 1933, 144.

Since polyvinyl ethyl ether yields oxalic acid on oxidation, Chalmers suggests that the structure of this ether, as well as those of its analogues, may be represented by

Whether or not the molecules contain "open" or "ring" structures is difficult to decide. As the polymers gave a small, but measurable, bromine absorption it might be assumed that an ethenoid linkage existed at one end, viz:

Quantitative measurements of bromine absorption, however, did not correspond with the degree of polymerization as indicated by cryoscopic determinations. Hence it appears probable that some polymers may possess a closed structure.

Polymerization of vinyl ethers may be carried out in the presence of compounds (such as vinyl chloride, vinyl acetate, styrene, acrylic nitrile or esters of acrylic or maleic acid) whose essential characteristic is that they contain a double bond in the aliphatic portion of their molecular structure.<sup>147</sup> The products may be employed as linings for apparatus.<sup>148</sup> Reaction may be effected also with the aid of acid-reacting catalysts, e.g., boron fluoride, stannic chloride, aluminum or zinc chloride, sulphuric or hydrochloric acid.<sup>149</sup> Other catalysts include hydrosilicates (Tonsil or Florida earth) or finely divided metals (for example, copper, iron, or nickel) on asbestos or silica gel.<sup>150</sup>

Divinyl ether is polymerized to a black, tarry resin by concentrated sulphuric acid and hydrolyzed rapidly to acetaldehyde by dilute hydrochloric acid. On heating divinyl ether to 70-150°C., using organic peroxides as catalysts, a highly viscous, transparent, resinous material is formed.<sup>151</sup> This latter transformation, however, is inhibited by ammonia.<sup>152</sup> N-Vinyl- $\alpha$ -methyldoline is rapidly transformed into a light yellow resinous mass on keeping.<sup>153</sup>

Vinyl or polyvinyl ethers may be employed in the production of impregnating, polishing, and finishing agents,<sup>154</sup> as components of lacquers,<sup>155</sup> in the preparation of adhesives for laminated glass,<sup>156</sup> as aids in the polymerization of butadiene hydrocarbons by alkali or alkaline earth metals,<sup>157</sup> and as insulating materials.<sup>158</sup> It has been proposed also to add polyvinyl ethers, particularly those from high-molecular-weight ethers, such as the vinyl ether of oleyl or cetyl alcohol, to lubricating oils.<sup>159</sup> Water-resistant films on cellulose esters or ethers may be secured by

### CHLOROVINYL ARSINES

Acetylene is absorbed by arsenic trichloride, employing aluminum chloride as a catalyst.<sup>101</sup> From the reaction mixture, after treatment with water, three arsenic derivatives may be isolated:  $\beta$ -chlorovinylchloroarsine,  $\text{CHCl}=\text{CHAsCl}_2$ ,  $\beta, \beta'$ -dichlorodivinylchloroarsine,  $(\text{CHCl}=\text{CH})_2\text{AsCl}$ , and  $\beta, \beta', \beta''$ -trichlorodivinylarsine,  $(\text{CHCl}=\text{CH})_3\text{As}$ . From the standpoint of synthetic resins the first of these derivatives is of interest.

Attempts to hydrolyze  $\beta$ -chlorovinylchloroarsine to the corresponding oxide resulted only in the formation of arsenious acid and acetylene. On passing hydrogen sulphide into a carbon tetrachloride solution of the dichloroarsine a thick viscous oil separated. The latter can be dissolved in carbon disulphide and on evaporation of the solvent a pale yellow, viscid liquid of garlic-like odor is obtained. On cooling, this solidified to a hard resin. Analysis indicated it to be  $\beta$ -chlorovinylarsenious sulphide,  $\text{CHCl}=\text{CHAsS}$ . In the preparation of this compound, ethyl alcohol may be substituted for carbon tetrachloride as the solvent for  $\beta$ -chlorovinylchloroarsine.<sup>102</sup>

### CARBON SUBOXIDE

The interest in carbon suboxide ( $\text{C}_3\text{O}_2$ ) from the point of view of synthetic resins lies in its marked tendency to polymerize. The unpolymerized substance is a gas at ordinary temperatures, which can be condensed to a liquid boiling at 7°C. and solidifying at about -110°C.<sup>103</sup> Its chemical properties in many respects are similar to those of a ketene (or diketene). Carbon suboxide unites with water to give malonic acid, with ammonia or amines to furnish amides, and with hydrogen chloride to form malonyl chloride.<sup>104</sup> From the reaction of this oxide with carboxylic acids are obtained mixed acid anhydrides.<sup>105</sup> For example, combination of acetic acid and carbon suboxide apparently gives rise to the compound:

which hydrolyzes to malonic and acetic acids.

The formation of this oxide, and other lower oxides of carbon or polymerized suboxide, was first noted when carbon monoxide was submitted to the action of electrical energy. In view of this fact, a brief discussion of this effect is given before taking up the subject of preparation.

## ACTION OF ELECTRIC DISCHARGES ON CARBON MONOXIDE

Brodie<sup>106</sup> observed that an electric current effected a contraction in volume of carbon monoxide, and at the same time carbon dioxide and a reddish-brown film (on the sides of the container) were formed. Analysis of the film indicated it to be an oxide of carbon, possibly  $C_2O_3$  or  $C_3O_2$ . He suggested that a series of "oxycarbons" existed, analogous to the acetylene hydrocarbons. Berthelot<sup>107</sup> also obtained the reddish-brown oxide of carbon in a similar manner, but found that heating decomposed the material into carbon monoxide and dioxide, and another oxide to which he assigned the formula  $C_3O_2$ . The latter oxide was secured when carbon monoxide was heated to temperatures of  $500-550^\circ C$ .<sup>108</sup>

Schutzenberg<sup>109</sup> reported that condensation of carbon monoxide by the silent electric discharge ceased as soon as the gas contained 10 per cent carbon dioxide, and that the solid product had the composition  $C_3O_2$ . Furthermore, condensation took place only when the electrodes of the discharge tube were acidulated water (dilute sulphuric acid). Substitution of such electrodes by metallic ones caused the reaction to cease. He therefore considered that the presence of a trace of moisture was essential for the reaction and that water vapor was carried through the glass discharge tube by the current. He later concluded that the water is formed from hydrogen and oxygen (probably generated at the electrodes) which penetrated the glass. Lunt and Mumford,<sup>170</sup> however, found that the type of electrode does not affect the reaction, as carbon monoxide is decomposed readily even when carefully dried. They also believed the brown solid produced by the discharge was not entirely polymerized malonic anhydride ( $C_3O_2$ ) but a mixture probably containing some carbon.

Lunt and Venkataswaran<sup>171</sup> state that decomposition of carbon monoxide can be represented by

and that on removing the solid oxide ( $C_3O_2$ ) from the reaction tube a hydrate,  $C_3O_2 \cdot xH_2O$  ( $x = 1.65$  or  $1.95$ ), is formed. Results obtained by Ott<sup>172</sup> however, indicate that the gases leaving a Siemens ozonizer contain only unimolecular suboxide

and the brown solid remaining is polymerized carbon suboxide.

**Preparation of Carbon Suboxide.** Dehydration of oxygenated organic compounds, particularly esters or acids, serves as a convenient procedure for the preparation of the suboxide. For example, on heating diethylmalonate with a large excess of phosphorus pentoxide to  $300^\circ C$ ., the following reaction occurs,<sup>173</sup>

Other esters of malonic acid (e.g., the dimethyl, dibenzyl, and diphenyl esters) and malonic acid itself also yield the suboxide when treated in a similar manner.<sup>174</sup> Dehalogenation of dibromomalonyl bromide with zinc,<sup>175</sup>

<sup>175</sup> H. Staudinger and H. Klever, *Ber.*, 1908, 41, 906.

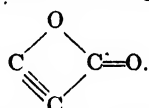

or treatment of malonyl chloride with metallic oxides (silver, lead, or zinc oxide)

are other methods.<sup>176</sup> Ott<sup>177</sup> secured good yields of the suboxide by pyrogenic decomposition of diacetyl tartaric acid or acetoxymaleic acid.

The more generally accepted constitution of carbon suboxide is that proposed by Diels and Wolf<sup>178</sup> who considered the compound to be a diketene having the

formula  $\text{O}=\text{C}=\text{C}=\text{C}=\text{O}$ . Michael<sup>179</sup> suggests a cyclic structure, .

**Polymerization of Carbon Suboxide.** Dry gaseous carbon suboxide is very stable, even at room temperature, when stored in glass containers whose surfaces have not been contaminated with the polymeric form.<sup>180</sup> The presence of mercury or of water vapor, however, effects polymerization of the gas. This reaction is probably a catalytic surface reaction as its velocity cannot be expressed by any simple mathematical formula. Stock and Stoltzenberg<sup>181</sup> believed polymerization of the suboxide to be autocatalytic, the speed depending upon the nature and surface of the containing vessel. They also report that phosphorus pentoxide exerts an accelerating effect.

Liquid carbon suboxide changes within 24 hours to a solid, amorphous, dark red substance which is soluble in water.<sup>182</sup> At 37°C. this polymer loses carbon dioxide and is converted into a material which is only partially soluble. On further heating carbon dioxide, carbon monoxide, and even some carbon suboxide, are evolved and the residue is apparently an oxide of carbon possessing a low oxygen content. Considerable quantities of the polymeric oxide were obtained by Jones and Robinson<sup>183</sup> when they attempted to purify diamyl and diethyl thiomalonates by distillation.

Two structural formulas have been suggested for polymerized carbon suboxide. Hartley<sup>184</sup> gives

and that proposed by Diels, Beckmann and Tonnie<sup>186</sup> is

Carbon suboxide reacts with liquid sulphur dioxide to give an unstable, white, sulphur-containing solid, the first step probably being

followed by polymerization of the latter compound.<sup>188</sup> Malonic acid and the suboxide yield a product resembling polymerized carbon suboxide. Tertiary bases unite with the oxide to form amorphous addition compounds, usually yellow to orange in color, and which are converted into resins on exposure to air. To illustrate, the product with quinine (1 mol of the base to 7 of the oxide) was orange-yellow in color, melted at about 135°C. (with decomposition), and resinified in 3 to 4 days in the air.

Carbon subsulphide, the sulphur analogue of carbon suboxide, can be prepared by conducting the vapors of carbon disulphide through an electric arc<sup>187</sup> or a glass tube heated to 600°C.<sup>188</sup> This sulphide is a liquid having a very disagreeable odor, freezes at -0.5°C., and on being heated to 120°C. changes to a hard black solid. It can be distilled (accompanied by some polymerization) under reduced pressure. Because its chemical properties are analogous to those exhibited by carbon suboxide, Stock and Praetorius<sup>189</sup> believed the constitution of the subsulphide could be represented by  $\text{S}=\text{C}=\text{C}=\text{C}=\text{S}$ .

## Chapter 51

# Polyvinyl Esters Polyvinyl Ester Co-Polymers

### INTRODUCTION

Esters of the hypothetical vinyl alcohol (e.g., vinyl chloride and vinyl acetate) polymerize to resins which are of particular interest because of their transparency and water-white color. The structure of these polymers may be represented as a long chain-molecule,<sup>1</sup>

in which R represents a halogen atom or an acyloxy group. Also the heteropolymers between the organic and inorganic esters of vinyl alcohol are adhesive and resistant to the action of acids and alkalies and have been suggested as coating agents and as the interlayers of safety glass.

All reactions intended to form vinyl alcohol<sup>2</sup> yield either acetaldehyde or ethylene oxide, both of which are tautomeric with the alcohol:

Vinyl esters, therefore, cannot be made by the usual esterification reaction of treating an alcohol with an acid.<sup>3</sup> Instead, acetylene is used as the source of the alcohol radical. The analogy of vinyl esters to other esters is seen when it is considered that olefins add acids to give saturated compounds, and acetylene unites with acids to yield unsaturated ones. Therefore, since olefins are the dehydration products of saturated alcohols, acetylene may be looked upon as the dehydration product of vinyl alcohol.

Polymers of the inorganic esters of vinyl alcohol, particularly the halides, have been known for many years but the organic esters, typically the acetate, are of more recent discovery. Polymers of the vinyl halides have, however, only limited technical application because of their low solubility and easy thermal decomposition. By employing them mainly in conjunction with organic esters of vinyl alcohol to form co-polymers in which these shortcomings are largely mitigated, plastics of some promise for use in coatings and moldings have been obtained. In this chapter the organic esters will be described first, then the inorganic esters and, finally, co-polymers of the two.

<sup>1</sup> An unsymmetrical combination might be expected also to occur, leading to chains,  $-\text{CH}_2-\text{CHR}-\text{CHR}-\text{CH}_2-\text{CH}_2-\text{CHR}-\text{CHR}-\text{CH}_2-$  or  $-\text{CH}_2-\text{CHR}-\text{CHR}-\text{CH}_2-\text{CHR}-\text{CH}_2-\text{CH}_2-\text{CHR}-$ . The latter, at any rate is ruled out for the polyvinyl halides, since these show microcrystallinity under x-ray examination. An unsymmetrical chain would not be expected to show this. See H. Staudinger, M. Brunner and W. Feisst, *Helv. Chim. Acta*, 1930, 13, 805; *Brit. Chem. Abs. A*, 1930, 1402.

<sup>2</sup> For the influence of potassium hydroxide on the formation of vinyl alcohol from acetaldehyde, see W. L. Evans and C. D. Looker, *J.A.C.S.*, 1921, 43, 1925.

<sup>3</sup> However, it has been reported that acetaldehyde reacts with acetic anhydride in the presence of inorganic acids to give vinyl acetate (G. A. Perkins, *British P.* 418,943, 1933, to Carbide & Carbon Chem. Corp.; *Brit. Chem. Abs. B*, 1935, 56. French P. 767,076. 1934; *Chem. Abs.*, 1935, 29, 177).

## POLYVINYL ORGANIC ESTERS

The most important organic vinyl ester is the acetate. Vinyl chloroacetate also has been studied to some extent, but other esters, such as the propionate, butyrate and trichloroacetate, have received little attention. Vinyl acetate is a mobile, colorless, non-toxic liquid boiling at 73°C.<sup>5</sup> It is formed by the reaction of acetylene and acetic acid in the presence of a catalyst. Many methods for the preparation of this ester have been proposed and the employment of a highly selective catalyst (to minimize secondary reactions) appears to be necessary.

## PRODUCTION OF ORGANIC VINYL ESTERS

When acetylene is passed into glacial acetic acid containing a small quantity of a mercury salt, particularly mercuric sulphate,<sup>6</sup> it is absorbed and converted into esters.<sup>7</sup> If the temperature is kept above about 70°C., ethylidene diacetate is formed to a large extent; at lower temperatures vinyl acetate is obtained, but usually in small proportions. It is probable that vinyl esters are formed first, but unless a low temperature is maintained or they are removed instantly from the reaction mixture, they react further with the acid to give esters of the hypothetical ethylidene glycol. Increased yields of vinyl acetate are secured if acetylene is conducted rapidly through acetic acid (and catalyst) heated to about 70°C.<sup>8</sup> In this manner the acetate is removed (as soon as produced) by the stream of acetylene which is passed through a condenser to recover the ester. Acetylene is recirculated through the catalyst mixture. Boron fluoride alone,<sup>9</sup> or mixed with hydrofluoric acid,<sup>10</sup> has been added to promote reaction in the presence of mercuric oxide. Vinyl butyrate and other esters can be made in a similar manner.<sup>11</sup>

The mercuric sulphate catalyst is more efficient if prepared by dissolving mercuric oxide in acetic acid and adding sulphuric acid, thus precipitating the sulphate in a finely divided state.<sup>12</sup> The catalyst is still more effective if precipitation is accomplished by addition of fuming sulphuric acid, since water formed by the reaction between mercuric oxide and acetic acid is eliminated by combination with sulphur trioxide.<sup>13</sup> A very active catalyst is obtained by treating mer-

<sup>4</sup> A brief description of the production and use of vinyl acetate is given by A. F. Cadenhead, *Chem. Met. Eng.*, 1933, 40, 185; R. Elliot, *Can. Chem. Met.*, 1934, 18, 173.

<sup>5</sup> Other physical constants of vinyl acetate are given by G. O. Morrison and T. P. G. Shaw (*Chem. Met. Eng.*, 1933, 40, 293, and *Trans. Electrochem. Soc.*, 1933, 63, 197; *Brit. Chem. <sup>7</sup> Study of the acetylene-acetic acid reaction was initiated to supply ethylidene diacetate for use as a solvent and as a source of acetic anhydride for the manufacture of cellulose acetate. Since vinyl acetate was always formed as a by-product, it eventually became of interest from the standpoint of the resins which it yielded by polymerisation, and processes were developed which gave this ester as the main product. curic oxide with a mixture of acetic acid and oleum. In this case the product is the mercury salt of acetylsulphuric acid.<sup>14</sup> With this compound a large yield of vinyl acetate is obtained, amounting to as much as 136 pounds per pound of mercuric oxide employed, provided the temperature of the reaction mixture is kept below 60°C.

Skirrow and Morrison<sup>15</sup> dissolved 20 parts of mercuric oxide in 2000 parts of glacial acetic acid and to this they added, at 85°C., 276 parts of a precipitant formed by dissolving 34 parts of sulphur trioxide in 242 parts of glacial acetic acid at about 20°C. The mixture was cooled to 25°C. and acetylene rapidly passed through it, the temperature gradually rising to about 35°C. The gas and entrained vapors were led through a condenser where vinyl acetate and acetic acid were removed. Acetylene and recovered acid were returned to the reaction zone. After a time the rate of absorption of acetylene slackened owing to reduction of the catalyst. The yield of vinyl acetate was approximately 70 per cent of theoretical based on the acetic acid used and, in this particular instance, amounted to 115 parts of acetate per part of mercuric oxide. If reaction was carried out at 70-100°C. and vinyl acetate returned to the reaction vessel, a high yield of ethylidene diacetate was obtained.<sup>16</sup>

A mixture of mercuric sulphate, sulphoacetic and acetic acid has been proposed as a catalyst.<sup>17</sup> Addition of ferric sulphate is stated to increase the yield of vinyl acetate.<sup>18</sup> Methionic acid,  $\text{CH}_3(\text{SO}_3\text{H})_2$ , and mercury sulphonates dissolved in acetic acid have been suggested also.<sup>19</sup> Zinc and cadmium acetates and benzoates have been used by Reppe<sup>20</sup> to catalyze reaction between acetylene and organic acids. Diluents, both liquid and gaseous, may be employed to reduce danger of explosions.

Skirrow and Morrison<sup>21</sup> found that mercuric orthophosphate is a good catalyst and less tar is formed with it than with mercuric sulphate.<sup>22</sup> One method of preparation consists in dissolving 3 parts of mercuric oxide in 100 parts of glacial acetic acid and adding 2.4 parts of orthophosphoric acid at a temperature of 80-90°C. A stream of acetylene is conducted through the mixture, heated to 78°C. under reflux, until absorption of the gas begins to decrease. On distillation, a total yield of vinyl acetate (including that carried over by the acetylene and re-

<sup>14</sup> A. J. van Peski (*Rec. trav. chim.*, 1921, 50, 103; *Chem. Abs.*, 1921, 15, 3455) reported that sulphur trioxide reacts with acetic acid at ordinary temperatures to give acetylsulphuric acid,  $\text{CH}_3\text{CO}\cdot\text{OSO}_3\text{H}$ , but at high temperatures sulphoacetic acid,  $\text{HSO}_3\text{CH}_2\text{COOH}$ , is formed.

<sup>22</sup> On the other hand, meta- and pyrophosphates favor high yields of ethylidene diacetates. Mercuric orthophosphate while active gives higher yields of vinyl acetate than the acetylsulphate catalyst, but it becomes inactive sooner so that the yield of ester per pound of mercuric oxide used is less than with the acetylsulphate catalyst. Also it is more expensive. See G. O. Morrison and T. P. G. Shaw, *loc. cit.*

covered) equal to about 95 per cent is obtained. Continuous operation can be effected if fresh catalyst is allowed to run into the reaction vessel before absorption of acetylene starts to slacken and, simultaneously, part of the spent mixture is removed for reactivation.<sup>24</sup>

A vapor-phase process, developed by Baum, Deutsch, Herrmann and Mugdan,<sup>24</sup> consists in passing acetylene and acetic acid vapor through a tube heated to about 200°C. and packed with activated charcoal impregnated with zinc or cadmium acetate. According to Ushakov and Feinstein,<sup>25</sup> the best ratio for the two reactants is 1 part by weight of acid to 9 parts of acetylene. This concentration may be obtained by saturating acetylene with acid vapor at 30°C. From 77 to 84 per cent of the theoretical yield of vinyl acetate resulted. In later investigations, the former workers<sup>26</sup> reported that increasing the rate of flow of the reactants increased the life of the catalyst and the yield of acetate over that of the diacetate. Ushakov and Feinstein noted, however, that a lower yield of vinyl acetate resulted on increasing the rate of flow.

Reaction between acetylene and acetic acid may take place in an inert solvent. Dykstra and Sly<sup>27</sup> passed acetylene into an autoclave containing a mixture of 2400 g. of acetic acid, 328 g. of finely divided mercuric sulphate and 3600 g. of refined kerosene which was stirred and kept at a temperature of 70-75°C. When absorption decreased, the temperature was raised and the rate of flow of acetylene increased. Vinyl acetate (with a sharp boiling range) was obtained by fractionating the distillate. Mugdan and Rost<sup>28</sup> suggest conducting acetylene and acetic acid vapor at 200-300°C. through a suspension of activated carbon and zinc or cadmium salts in a high-boiling hydrocarbon.

Ethylidene diacetate may be used as a source of vinyl acetate. By dissolving about 10 per cent by weight of sulphur dioxide or about 0.4 per cent of syrupy phosphoric acid in the diacetate and heating at 100-170°C., acetaldehyde, acetic anhydride and 15-25 per cent of vinyl acetate are formed.<sup>29</sup>

Vinyl organic esters, which contain hydrophile groups (e.g., hydroxyl, carboxyl and sulphy), have been prepared by heating vinyl chloride with salts of substituted organic acids.<sup>30</sup> Thus, vinyl chloride and monopotassium succinate mixed with toluene and heated in an autoclave at 100-130°C. gave vinyl succinic ester.

#### POLYMERIZATION OF VINYL ACETATE

In the cold, vinyl acetate does not polymerize in the absence of light but, when illuminated, transformation is effected more or less rapidly depending upon the kind of light. When heated to 100°C., or higher, acetate of ordinary purity will

polymerize in the dark and reaction is accelerated by oxygen or peroxides.<sup>31</sup> According to Staudinger and Schwalbach,<sup>32</sup> a trace of oxygen or peroxide is essential for thermal polymerization. A sample of vinyl acetate, distilled in an atmosphere of nitrogen with complete exclusion of oxygen, failed to polymerize when heated at 100°C. in a sealed tube for 6 weeks, but eventually did so when the temperature was raised to 180°C. In the presence of air the same material polymerized at 100°C. in a day.

The influence of oxygen on polymerization is quite different when the reaction mixture (in quartz vessels) is irradiated in the cold with light from a mercury arc. Under these conditions, reaction proceeds more rapidly in the absence of oxygen or in an atmosphere of nitrogen or carbon dioxide.<sup>33</sup> Oxygen, therefore, inhibits photopolymerization of vinyl acetate but accelerates thermal polymerization.<sup>34</sup> On the other hand, oxygen does not retard the photopolymerization of styrene or isoprene.

Although many unsaturated hydrocarbons are polymerized at ordinary temperature by Florida earth, inorganic halides and organic amines, these substances apparently have no influence on vinyl acetate.

#### DEGREE OF POLYMERIZATION OF VINYL ACETATE

Polyvinyl acetate of the highest degree of polymerization has a molecular weight of about 80,000. This material was made by irradiation of the pure ester in an atmosphere of nitrogen and corresponds to a macromolecule containing about 900 monomeric units.<sup>35</sup> Such a resin swells strongly in solvents, is difficult to dissolve and gives solutions of very high viscosity. When heated at 100°C. in the presence of oxygen, vinyl acetate yields a polymer of average molecular weight of about 20,000; with benzoyl peroxide a resin having a molecular weight of about 6000 is obtained.

Polymerization in solution gives, as a rule, products of relatively low molecular weight and reaction is slower. Staudinger and Schwalbach irradiated a chloroform solution of vinyl acetate and, after evaporation of the solvent, the residue (mol. wt. about 3000) was a white, brittle mass which could be powdered easily. Starkweather and Taylor<sup>36</sup> used toluene as a solvent. They believe that the retarding action of the solvent can be ascribed to the activated molecules of the ester giving up their energy to the solvent molecules before combining with other vinyl acetate molecules.

Solvents differ in their inhibiting effect on the reaction and in their influence on the molecular weight of the product. In petroleum ether (b.p. 30-50°C.), transformation occurs rapidly and the molecular weight of the polymer may be as high as 20,000. In this case the polymer is insoluble in the solvent and separates almost as soon as formed. On the other hand, chloroform, chlorobenzene, alcohol, acetone and toluene retard polymerization and give rise to low-molecular weight polymers. With cyclohexanol and cyclohexane as solvents, colored substances are obtained, that from the former being greenish, and from the latter, light red. Polyvinyl acetate obtained by polymerization in chloroform has been shown by Staudinger and Schwalbach to contain chlorine. They assume that hydrogen

<sup>31</sup> F. Klatte and A. Rollett, U. S. P. 1,241,738, Oct. 2, 1917, to Chem. Fabrik. Griesheim-Elektron; *J.A.C.I.*, 1917, 36, 1195. German P. 281,657, 1915 and 281,659, 1914; *J.S.C.I.*, 1915, 34, 628. French P. 474,069, 1914; *J.S.C.I.*, 1915, 34, 724. British P. 15,271, 1915.

<sup>32</sup> H. Staudinger and A. Schwalbach, *Ann.*, 1931, 488, 8.

<sup>34</sup> The inhibiting action of oxygen on the photopolymerization of vinyl compounds was observed also by H. S. Taylor and A. A. Vernon, *J.A.C.S.*, 1931, 53, 2527.

<sup>35</sup> H. Staudinger and A. Schwalbach, *loc. cit.*

<sup>36</sup> H. W. Starkweather and G. B. Taylor, *J.A.C.S.*, 1930, 52, 4706.

chloride, resulting from the photochemical decomposition of chloroform, unites with the end valences of the polymer-chains.

Polyvinyl acetate cannot be obtained in a crystalline condition and, according to x-ray evidence, is completely amorphous. In comparison with rubber, it is not elastic. However, polymers having from 150 to 250 vinyl units per molecule are elastic when heated and can be drawn into threads. Under the same conditions, polyacetates containing 30 to 70 vinyl units are not elastic and those having 300 or more units decompose before they soften sufficiently to exhibit elasticity. Unlike rubber, even the stretched polymers show no fiber diagram on x-ray examination.<sup>87</sup> When swollen by treatment with a solvent, polyvinyl acetate does show elastic properties.

While irradiating a benzene solution of vinyl acetate, Staudinger and Schwalbach<sup>88</sup> noticed traces of insoluble, transparent particles on the portion of the quartz tube nearest the light. Insoluble products were obtained also when

FIG. 131.—A Piece of Vinylite Resin Undergoing Fatigue Test.

vinyl acetate was heated at 180°C. in the presence of oxygen, or at temperatures greater than 200°C. in the absence of oxygen. It was assumed that acetic anhydride was split out between separate chains of the macromolecules thus building up 3-dimensional structures.

#### VARIOUS METHODS OF POLYMERIZATION

One continuous process consists in allowing a vinyl ester to descend a long tube, whose upper part is kept at a temperature just below the boiling point of the liquid by means of cooling devices and whose lower part is maintained at about 200°C. by heating coils. The hot product is ejected at the bottom upon a belt conveyor to cool.<sup>89</sup> Polyvinyl esters, while hot, may be pressed into molds to cool or they may be extruded through nozzles, cooled and disintegrated to form a molding composition.<sup>90</sup>

As previously indicated, vinyl esters polymerize under the influence of heat and light. Klatte and Rollett<sup>91</sup> exposed vinyl acetate and chloroacetate to direct sunlight or to light from a mercury arc, and the esters were eventually converted

<sup>91</sup> F. Klatte and A. Rollett, *loc. cit.*

to solid resins. A shorter exposure to light produced thick syrups which when further exposed in the form of thin layers gave transparent films. Polymerization is accelerated by the addition of oxidizing agents, the most active ones being organic peroxides or ozonides and organic acid anhydrides in conjunction with percarbonates, perborates, silver oxide or other metallic oxides capable of yielding oxygen. Benzoyl peroxide is an efficient catalyst. Incorporation of 0.05-0.1 per cent of this peroxide with vinyl chloroacetate, followed by careful heating, gave a thick syrup in a short time. Polymerization began at 80-100°C. with a rapid rise in temperature, so that the reaction vessel had to be cooled. If the ester was diluted with an indifferent solvent (such as chlorobenzene) the progress of the reaction was moderated. The thick syrup could be further changed to a hard resin by the action of light or by subjecting it to vacuum distillation to remove unpolymerized ester. The final resin could be modified by adding camphor to the ester before treatment.

Schrivver<sup>42</sup> reports acetyl benzoyl peroxide is more active than benzoyl peroxide, since 0.15-0.3 per cent of it (based on the weight of vinyl ester) effected the same degree of polymerization as 1.0 per cent of benzoyl peroxide. Furthermore, the acetyl derivative is more completely used up and is more easily removed from the final product because it is more readily decomposed. Acetyl benzoyl peroxide was made by passing dry air or oxygen through a mixture of benzaldehyde and acetic acid anhydride.

Blaikie<sup>43</sup> prepared similar catalysts by the reaction of aliphatic anhydrides with hydrogen peroxide, sodium peroxide, or true per-salts, i.e., those salts yielding hydrogen peroxide on hydrolysis. A solvent (e.g., vinyl acetate) in which the non-catalytic by-products are insoluble may be employed.

Vinyl resins may be made directly from acetylene without the necessity of isolating the vinyl ester.<sup>44</sup> Acetylene is passed into acetic acid under pressure in the presence of small amounts of metals or metallic compounds such as magnesium, tin or copper; iodine or hydriodic acid; boron compounds or organic acid anhydrides. If acetylene is diluted with an inert gas (nitrogen, benzene or petroleum vapor) the pressure can be increased to 10-15 atmospheres and reaction correspondingly increased without risk of explosion. For example, 26-28 parts of acetylene were gradually passed into a mixture of 50 parts of acetic acid and 1 part of acetic anhydride. The charge was heated at 40-60°C. and the pressure was raised to 5 atmospheres by the introduction of nitrogen. The product consisted of 75 parts of vinyl acetate and 3-5 parts of ethylidene diacetate. If the temperature was then increased to 10 atmospheres or more, the ester was polymerized to bodies which varied in consistency from semi-solids to more or less tough resins.

If vinyl acetate is treated with 0.1 per cent of benzoyl peroxide under pressure and at temperatures up to 100°C. for 2 hours, only 50-60 per cent of the ester is polymerized. The proportion of polymer may be increased (under the same conditions) to about 80 per cent by using the catalyst in the presence of water.<sup>45</sup> The latter also exerts a favorable influence when polymerization is effected in the

The later it was added the harder the resin. (French P. 730,348, 1923, to Soc. Nobel française; *Chem. Abs.*, 1934, 28, 915.)

absence of other catalysts. Solutions of hydrogen peroxide, perborates, percarbonates, barium peroxide or calcium peroxide in water are effective and their activity may be enhanced by the addition of alkaline substances such as caustic soda, alkaline phosphates or borates, magnesium or zinc oxide, ammonia or hexamethylenetetramine. For example, 100 parts of vinyl acetate may be heated in an autoclave for 2 hours at 100°C. with (a) 1.5 parts of a 3 per cent solution of hydrogen peroxide, or (b) 0.25 parts of sodium borate and 1.5 parts of 5 per cent hydrogen peroxide solution to form clear masses which, after removal of unpolymerized material by steam distillation, are hard and resin-like. Vinyl butyrate heated with hydrogen peroxide under similar conditions produces a more elastic mass than that from the acetate. Aqueous solutions of partly polymerized vinyl esters may be thickened by treatment with boric acid, a boric ester or hypoborofluoric acid. Gelatinization can be made to take place by this means.<sup>46</sup>

Polymerization of vinyl esters in the presence of catalysts is highly exothermic and often proceeds with almost explosive force. With small batches, one can resort to cooling but this may not be effective on a large scale. Herrmann and Haehnel<sup>47</sup> overcame this difficulty by starting with a small portion of a mixture of vinyl ester and catalyst. This was heated (under reflux) until reaction began, and then the remainder was run in at such a rate that the temperature remained slightly below the boiling point of the ester. At the same time an equal volume of the partly polymerized material was transferred from the reaction vessel to a finishing vessel (also provided with reflux) in which transformation to the polyester was completed. Alcohol may be introduced simultaneously into the finishing vessel and an alcoholic solution of polyvinyl acetate thus formed.

Polymerization in a solvent is slower and more easily controlled and reaction may be stopped before the polymer becomes insoluble in the solvent. For example, equal parts of vinyl acetate and alcohol, together with a small proportion of benzoyl peroxide, may be heated under reflux and a colorless, viscous lacquer of 50 per cent concentration obtained.<sup>48</sup> Blaikie, Morrison and Shaw<sup>49</sup> made polymers of desired softening points and viscosities by regulating the concentration of the unpolymerized vinyl compound present during reaction.

Alcohol containing about 5 per cent of water or turpentine seems to be a better solvent for polyvinyl acetate than alcohol alone.<sup>50</sup> Highly polymerized ester which is insoluble in alcohol may be dispersed in this liquid by first dissolving it in a non-alcoholic solvent, distilling the solution and adding alcohol gradually during distillation until the non-alcoholic solvent has been replaced. An acetic acid solution may be treated in this manner until all the acid has been eliminated. A stiff gel-like paste is formed which can be thinned with more alcohol and used as a lacquer.<sup>51</sup> Addition of a small amount of water to the paste causes it to disperse more easily in alcohol than an unwatered paste.<sup>52</sup>

Another method for effecting polymerization of vinyl compounds in solution consists in heating a portion of the mixture, say 100 g., on a water bath until reac-

tion begins and then controlling its course by the gradual addition of the remainder of the solution.<sup>55</sup> For example, a mixture containing 900 g. of vinyl acetate, 600 g. of toluene and 4.5 g. of benzoyl peroxide, treated in this way over a period of about 12 hours, gave an 89 per cent yield of polymer. Butyl acetate, ethyl acetate, benzene, chlorobenzene, ethyl dichloride or methyl ethyl ketone may be used instead of toluene. Di- or trichloroethylene have been suggested also.<sup>56</sup> If di-n-butyl ether is the solvent, the polymer separates as a lower layer and can be dissolved in toluene after decanting the ether. Vinyl chloroacetate gives a somewhat higher yield of polymer by the above procedure than does the acetate. Soluble polymers of vinyl propionate and butyrate can be made also from the corresponding esters in solution, whereas the products formed in the absence of a solvent are usually insoluble. Rushchinskii<sup>57</sup> has suggested the preparation of polyvinyl acetate by heating the monomer in an autoclave in the presence of ether or low-boiling petroleum hydrocarbons.

Lawson<sup>58</sup> recommended the use of an ozone-treated solvent, e.g., methanol through which an ozone-air mixture was passed for 2 hours. Twenty-five g. of vinyl acetate in 44 g. of this liquid, heated for 5 hours under pressure at 90°C., gave a yield of 48 per cent of the polymer. In like manner, chloroacetate showed a 72 per cent conversion.

Application of high pressures increases the velocity of polymerization of vinyl acetate and the rate of reaction approximates one of a first order. It also lowers the temperature at which reaction begins and, under very high pressure, transformation may occur without recourse to heating.<sup>57</sup> Pressures up to 25,000 atmospheres have been suggested.<sup>59</sup>

Polyvinyl esters may contain small proportions of the monomer, acetaldehyde and the acid from which the ester was made. These substances can be removed by steam distillation with subsequent heating (*in vacuo*) of the resin to dry it<sup>60</sup> or by dissolving the resin in a liquid and distilling the solution.<sup>60</sup> Water-soluble material can be eliminated by exposing the resin in a finely divided state (raspings, clippings, threads or thin sheets) to water for several hours.<sup>61</sup> Final traces of acid may be made harmless by adding soluble bases such as diphenylguanidine or phenylhydrazine.<sup>62</sup> Since monomeric vinyl esters are readily hydrolyzed<sup>63</sup> (to acetic acid and acetaldehyde) when heated in acid solution in the presence of mercury compounds, this step can be employed to free the polymer from unpolymerized ester.<sup>64</sup>
